Voxel-Based Morphometry and Diffusion Tensor Imaging of the Optic Pathway in Primary Open-Angle Glaucoma: A Preliminary Study

BACKGROUND AND PURPOSE: Neuropathologic studies in experimental and human glaucoma have demonstrated degenerative changes in the optic pathway. The purpose of this study was to assess the optic pathway in POAG by using VBM and DTI.

MATERIALS AND METHODS: Eighteen patients 57.05 ± 11.38 years of age with POAG of 8.30 ± 5.14 years' duration and 18 control subjects underwent a complete ophthalmologic examination, including quantification of the RNFLT by using Stratus OCT 3, and brain imaging. The imaging protocol consisted of a T1-weighted high-resolution 3D spoiled gradient-echo sequence and a multisection spin-echo-planar diffusion-weighted sequence. Data preprocessing and analysis were performed by using Matlab 7.0 and SPM 5.

RESULTS: Left temporal and right nasal RNFLT were significantly thinner than right temporal and left nasal RNFLT. In patients, VBM revealed a significant reduction in the left visual cortex volume, the left lateral geniculate nucleus, and the intracranial part of the ONs and the chiasma. In addition, a significant decrease of FA was observed in the inferior fronto-occipital fasciculus, the longitudinal and inferior frontal fasciculi, the putamen, the caudate nucleus, the anterior and posterior thalamic radiations, and the anterior and posterior limbs of the internal capsule of the left hemisphere ($P < .05$).

CONCLUSIONS: Neurodegenerative changes of the optic pathway and several brain areas associated with the visual system can be observed by using VBM and DTI in patients with POAG, suggesting that glaucoma is a complex neurologic disease.

ABBREVIATIONS: BA = Brodmann area; C/D = cup to disc ratio; FA = fractional anisotropy; FMRIB = Functional MR Imaging of the Brain; GM = gray matter; LGN = lateral geniculate nucleus; MD = mean diffusivity; MNI = Montreal Neurologic Institute; OCT = optical coherence tomography; ON = optic nerve; POAG = primary open-angle glaucoma; PSD = pattern SD; RNFLT = peripapillary retinal nerve fiber layer thickness; SAR = signal-intensity average ratio; VBM = voxel-based morphometry; WMH = white matter hyperintensities

POAG is a progressive optic neuropathy characterized by irreversible loss of retinal ganglion cells, degeneration of their axons in the ON, and visual field loss.¹ It is a significant cause of blindness throughout the world, and by 2020, it is predicted that close to 60 million people will have POAG.² Raised intraocular pressure is known to be the major risk factor for glaucoma, but despite effective medical and surgical treatment to reduce intraocular pressure, progressive vision loss is common among patients with glaucoma.³ These observations suggest that mechanisms independent of intraocular pressure are also implicated in the progression of the disease.⁴ Neurodegeneration may play an important role in the pathogenesis and progression of glaucoma,^{4,5} and a variety of neuroprotective agents are under investigation for application in glaucoma treatment. The fundamental common process observed in neurodegenerative disorders is death of a specific neuron population followed by antegrade or retrograde trans-synaptic spread of degeneration (wallerian degeneration) from abnormal to normal neurons.⁴

Experimental studies in animal models and postmortem studies of human glaucoma provide evidence of the fundamental process of neurodegeneration by demonstrating the death of retinal ganglion cells and the degeneration of the ON, LGN, and visual cortex.⁵⁻⁷ The development of imaging modalities for the early detection of these changes in vivo could be very important for more accurate evaluation of the disease severity and assessment of the therapeutic efficacy of treatment strategies. Conventional MR imaging and magnetization-transfer imaging have been used in the evaluation of POAG and, with the use of region-of-interest methods, have demonstrated ON atrophy and a decrease of the magnetization-transfer ratio suggestive of degeneration in the chiasma and the visual cortex.⁸

VBM is an objective automated technique that assesses brain volume changes throughout the whole brain without a priori identification of a region of interest. This approach is not biased toward any particular region of the brain and permits the identification of unsuspected potential regional structural changes in the brain.⁹ VBM has been used in the study of patients with long-standing retinal field defects in whom it has demonstrated regional changes in the cortical GM volume.¹⁰

DTI provides noninvasive measures of microstructural WM integrity by measuring molecular diffusion and is highly sensitive in detecting axonal injury.^{11,12} DTI has been used in

the evaluation of WM degeneration, and changes in diffusivity scalars have been found useful in the differential diagnosis between primary and wallerian (secondary) degeneration.¹³ DTI by using region-of-interest analysis has been used in the evaluation of the ON and the optic tract in experimental glaucoma and transient retinal ischemia, demonstrating changes in the diffusivity scalars compatible with wallerian degeneration.^{7,14,15} High-field-strength DTI by using region-of-interest analysis in human glaucoma demonstrated a correlation between diffusivity scalars and glaucoma stage.¹⁶ Voxelwise statistical analysis of DTI scalars assesses changes throughout the whole brain without a priori identification of a region of interest.⁹

Although POAG is a significant cause of blindness, it has not been an area of intensive research interest in imaging, and to the authors' knowledge, no other study has used the above-mentioned imaging techniques to assess the human brain in the setting of this disease. The present study was designed to evaluate possible optic pathway neurodegeneration by using VBM and voxel-based DTI analysis in patients with POAG.

Materials and Methods

Subjects

Eighteen patients with bilateral POAG, 14 men and 4 women, 37–75 years of age (mean age, 57.05 ± 11.38 years), and 18 age- and sex-matched disease-free control subjects were enrolled in the study. All patients fulfilled the diagnostic criteria for POAG of the American Academy of Ophthalmology, which are intraocular pressure ≥ 21 mm Hg, glaucomatous optic disc and visual field abnormalities, and a nonoccludable anterior chamber angle without characteristics of congenital or secondary glaucoma.¹⁷ In patients, the disease duration from the diagnosis of glaucoma was 1–20 years (mean, 8.30 ± 5.14 years). To rule out strokes, microhemorrhages, demyelination, and small-vessel diseases, which can have marked impact on DTI and VBM parameters, we excluded patients with demyelinating disease, autoimmune disease (vasculitis), a history or clinical signs of cardiovascular disease, peripheral artery disease, diabetes mellitus (fasting plasma glucose concentration, ≥ 126 mg dL⁻¹, or use of antidiabetic medications), and hypertension (arterial blood pressure, $\geq 140/90$ mm Hg, or use of antihypertensive medications). Furthermore, to rule out retinal nerve-fiber-layer thickness changes or perimetric findings not directly related to POAG, we excluded patients with a history of ophthalmic surgery (including refractive surgery), ophthalmic or orbital trauma, ON atrophy, uveitis, diabetic retinopathy, any form of cystoid macular edema, age-related macular degeneration, refractive errors in myopia, or hypermetropia >3.00 diopters and in astigmatism >1.00 diopters. Also patients with exfoliative glaucoma, acute glaucoma, or congenital glaucoma were excluded. Patients with any degree or form of cataract were also excluded to avoid any effects of cataracts on perimetric findings.

Clinical Examination

All patients and control subjects underwent complete ophthalmologic examination including visual acuity (optotype Snellen), intraocular pressure measurement (Goldmann tonometer), gonioscopy, funduscopy with evaluation of the C/D, by using the Discam imaging system (Marcher Enterprises, Hereford, United Kingdom), assessment of visual fields (Humphrey, 24–2: mean deviation, PSD), and quantification of RNFLT by using Stratus OCT 3, Version 4 (Carl

Zeiss, San Diego, California). Before the OCT scan, all participants were subjected to pupillary dilation with 0.5% tropicamide and 0.5% phenylephrine. They then underwent optic disc scanning by using the fast RNFLT protocol, which is designed for the measurement of RNFLT. The fast RNFLT protocol compresses the 3 sequential circular scans of 3.4-mm radius of the RNFLT protocol into 1 scan, performed in 1.92 seconds. The average RNFLT was extracted from the fast RNFLT protocol at a distance of 3.4 mm from the center of the optic disc, for each of the 4 peripupillary quadrants (inferior, superior, nasal, and temporal). The universal RNFLT (mean RNFLT score for all quadrants) was also recorded. Informed consent was obtained from all patients, and the study was approved by the institutional review board and was Health Insurance Portability and Accountability Act—compliant.

Imaging Protocol

All MR imaging examinations were performed on the same 1.5T unit (Gyrosan Intera; Philips Healthcare, Best, the Netherlands) by using a quadrature head coil. Subjects were asked to close their eyes and avoid any deliberate eye movements during image acquisition. The imaging protocol consisted of the following: 1) T1-weighted high-resolution ($1 \times 1 \times 1$ mm) 3D spoiled gradient-echo sequence (TR, 25 ms; TE, 4.6 ms; bandwidth 151.4 Hz/pixel; acquisition matrix, 256×228 ; FOV, 220 mm; SAR, $<1.9/0$ W/kg; scanning time, 5 minutes and 43 seconds; number of signal intensity averages, 1), which was used for structural imaging; 2) a single-shot multisection spin-echo-planar sequence (TR, 9807 ms; TE, 131 ms; FOV, 230 mm; bandwidth, 13.8 Hz/pixel; matrix, 128×128 ; section thickness, 3 mm; maximum b-value, 700 s/mm²; 16 noncollinear diffusion directions; SAR, $<0.3/0$ W/kg; scanning time, 5 minutes and 34 seconds; number of signal intensity averages, 2; intersection gap, 0), which was used for DTI; and 3) a sagittal T2-weighted FLAIR sequence (TR, 6300 ms; TE, 120 ms; FOV, 250 mm; matrix, 256×256 ; bandwidth, 336.7 Hz/pixel; section thickness, 6 mm; intersection gap, 0.6; SAR, $<0.7/0$ W/kg; scanning time, 2 minutes and 50 seconds; number of signal intensity averages, 2), which was used for evaluation of WMH.

Image Analysis

Morphometric preprocessing and analysis were performed by using Matlab, Version 7.0 (MathWorks, Natick, Massachusetts) and SPM 5 (Wellcome Department of Cognitive Neurology, London, UK). Preprocessing for the T1-weighted images involved the following: first, spatial normalization of all images to the T1 MNI template supplied with the SPM. The images were then segmented into GM, WM, and CSF compartments. Modulation of the segmented images was performed applying the Jacobian determinants derived from the spatial normalization step. Finally, GM, WM, and CSF partitions were smoothed with a Gaussian filter of $8 \times 8 \times 8$ mm full-width at half maximum. Volume changes in patients with POAG relative to the control group were assessed at every brain voxel by estimating the *t*-score at a significance threshold of $P = .05$ corrected for multiple comparisons by using the false discovery rate approach.

Voxelwise statistical analysis of the FA and MD was performed by using tract-based spatial statistics, part of the FMRIB Software Library (<http://www.fmrib.ox.ac.uk/analysis/techrep/tr04ss2/tr04ss2/node19.html>).¹⁸ First, FA and MD images were created by fitting a tensor model to the raw diffusion data by using the diffusion toolbox in FMRIB, and then they were brain-extracted by using the brain-extraction tool.¹⁹ The FA and MD data of all the subjects were then aligned into a common space (FMRIB58_FA) by using the nonlinear

image registration tool in FMRIB,²⁰ which uses a b-spline representation of the registration warp field.²¹ Next, the mean FA image was created and thinned to create a mean FA skeleton, which represents the centers of all tracts common to the group. The aligned FA and MD data of each subject were then projected onto this skeleton, and the resulting data were fed into voxelwise cross-subject statistics by using a permutation-based nonparametric inference method (RANDOMIZE, Version 2.01, a tool of FSL software package). The map-wise false-positive rate (family-wise error) was controlled with a P value $<.05$. One radiologist (L.C.T.) who was unaware of the clinical status of the patients and the control subjects evaluated the presence and the numbers of WMH on sagittal FLAIR sequences. The B0 images were also examined for evidence of T2* abnormalities (blood/calcifications).

Statistical Analysis

All results were expressed as mean $\pm$ SD. The single-sample Kolmogorov-Smirnov test was used to estimate the distribution characteristics of the variables. The combined variables equal to the average of the RNFLT values of the nasal quadrant of 1 eye and the temporal quadrant of the other eye were calculated. The differences between clinical values of temporal and nasal RNFLT of the right and left eyes, the combined RNFLT, the C/D, mean deviation, visual acuity and PSD, and differences in WMH between patients and controls were estimated by using a 2-tailed paired t test. Multilinear regression analysis was used to evaluate the relationships between disease laterality (right eye versus left eye) and the clinical variables. Statistical analyses were performed by using the Statistical Package for the Social Sciences software, Version 16.0 (SPSS, Chicago, Illinois). A P value $<.05$ was accepted as significant.

Table 3: Location and size of significantly reduced GM areas in patients with glaucoma, relative to controls^a

Volume (mm ³)	Z Score	Talairach Coordinates (x, y, z) (mm)	Region
1912	4.99	−6, −90, 4	Left calcarine
4000	4.69	16, 10, 14	Right caudate

^a Talairach coordinates and z scores are for voxels of maximal statistical significance for each region.

Results

The normality of distribution of the variables was confirmed by the Kolmogorov-Smirnov test. Univariate analysis showed that in the left eye, the RNFLT was thinner in the temporal than in the nasal quadrant, whereas in the right eye, the RNFLT was thinner in the nasal than in the temporal quadrant ($P < .001$) (Tables 1 and 2). The combined left temporal and right nasal RNFLT (48.8 $\pm$ 13.82 μm) were significantly thinner than the right temporal and left nasal RNFLT (71.16 $\pm$ 16.36 μm) ($P < .001$). No significant differences were observed in the C/D, mean deviation, and PSD between the right and left eyes (Table 2). Multilinear regression analysis indicated that disease laterality was associated only with temporal RNFLT ($P < .001$) and nasal RNFLT ($P < .001$), and it was independent of the C/D ($P = .397$), mean deviation ($P = .942$), and PSD ($P = .367$). There was a trend toward a greater number of WMH in patients (total, 162; mean, 9.0 $\pm$ 9.8) compared with controls (total, 71; mean, 3.9 $\pm$ 2.8) ($P = .056$).

VBM revealed a significant volume reduction in patients with POAG in the intracranial part of the ONs and the chiasma in the left LGN and left visual cortex (BA17, BA18) ($P < .05$) (Table 3 and Figs 1 and 2). A significant decrease of FA was observed in patients with POAG in the inferior fronto-occipital fasciculus, the longitudinal and inferior frontal fasciculi, the putamen, the caudate nucleus, the anterior and posterior thalamic radiations, and the anterior and posterior limbs of the internal capsule of the left hemisphere (Table 4 and Fig 3) ($P < .05$). No MD differences were detected between patients with POAG and control subjects.

Discussion

Glaucoma affects nearly 60 million individuals worldwide, and it is one of the leading causes of irreversible blindness. The pathologic hallmark of glaucoma is retinal ganglion cell loss. Although the retinal cell body lies within the eye, the larger part of its axon lies outside the eye, forming the ON, the chiasma, and the optic tract; 90% of the retinal ganglion cells terminate in the LGN, the major relay station between the

retina and the visual cortex. The cells of the LGN project to the primary visual cortex, which corresponds to BA 17. The primary visual cortex sends a large proportion of its connections to the secondary visual cortex, BAs 18 and 19. Neurons in the central nervous system may undergo atrophy or cell shrinkage in response to a given insult, and persistence of the pathologic state may lead to neuronal death. Wallerian degeneration is a well-known process in neurodegenerative diseases.⁵ Consequently, glaucomatous optic neuropathy can produce loss not only of retinal ganglion cells and their axons but also of neural cells in the LGN and, to some extent, even of the visual cortex. The present study, by using VBM and voxel-based DTI analysis in patients with POAG, demonstrated several structural changes in the optic pathway.

VBM demonstrated a significant reduction in the intracranial part of the ONs and the chiasma. A previous study by

using magnetization-transfer imaging and conventional MR imaging also demonstrated ON atrophy and degeneration of the chiasma in patients with POAG.⁸ In agreement with the present study, Kashiwagi et al,²² by using conventional MR imaging, demonstrated atrophy of the retrobulbar ON in patients with POAG and normal-tension glaucoma. The diameter of the ON and the chiasma height were both less in patients with glaucoma. Both parameters were also significantly correlated with mean deviation and the C/D.²²

Another finding of the present study was a significant reduction in volume of the left LGN. Experimental studies in monkey glaucoma have demonstrated ON fiber loss associated with LGN degenerative changes, with overall LGN shrinkage and reduced neuron size.²³ A postmortem study of human glaucoma with bilateral visual-field loss, by using histomorphometry and ex vivo MR imaging, demonstrated reduced LGN and neuron size.⁵ Gupta et al,²⁴ after obtaining LGN height measurements in vivo by 1.5T MR imaging, reported LGN atrophy in patients with glaucoma with symmetric bilateral visual-field defects. In contrast, in the present study, more pronounced atrophy was found on the left side, and this is probably related to the more pronounced atrophy of the right nasal and left temporal retinal fibers found with OCT and may be due to the small sample, because POAG is often a bilateral condition.

In addition to LGN changes, a significant reduction of GM was demonstrated in the left visual cortex (BA17, BA18). Transneuronal degeneration has been suggested as the main mechanism responsible for cortical thinning in patients with glaucoma-induced ON damage.¹⁰ A recent study showed degenerative changes in the visual cortex of 8 patients with POAG and 9 patients with age-related macular degeneration by using VBM.¹⁰ Another study in patients with POAG demonstrated a low magnetization-transfer ratio in the chiasma and the GM and WM of the calcarine fissure, suggesting optic-pathway degeneration.⁸ In the present study, the reduction of GM, predominately in the left visual cortex, may be explained by the most pronounced atrophy of the right nasal and left temporal retinal fibers found with OCT. These fibers project to the left LGN and the left visual cortex (BA17, BA18). This lateralization may again be related to the small sample because POAG is often a bilateral condition.

Voxel-based DTI demonstrated a significant unilateral decrease of FA at the left hemisphere in the inferior fronto-occipital fasciculus, the longitudinal and inferior frontal fasciculi, putamen, caudate nucleus, anterior and posterior thalamic radiations, and anterior and posterior limbs of the internal capsule. DTI has been successfully applied to detect ON changes occurring in the rat model of glaucoma in which a reduction of FA was observed.⁷ Region-of-interest analysis with 3T DTI applied in the study of human glaucoma demonstrated a correlation between diffusivity scalars of the ON and optic radiation and glaucoma stage.¹⁶ WM fibers of the inferior fronto-occipital fasciculus reach the superior frontal region (BA 8 and BA 6), and caudally these fibers reach the inferior parietal lobule and the dorsal parietal and occipital areas (BA 7, BA 39, BA 19). All these areas have been shown to play a role in visuospatial function.²⁵ The inferior longitudinal fasciculus connects the occipital and the anterior temporal lobes. The inferior longitudinal fasciculus originates in the

anterior temporal lobe, passes through the parahippocampal gyrus, and finally reaches the pulvinar. Tractography of the

human brain has demonstrated that function of the inferior longitudinal fasciculus is highly related to visual memory, and its possible damage causes impairment of visual memory.²⁶ In the present study, the pronounced FA reduction in the left hemisphere was in accordance with the OCT findings, which demonstrated a significantly thinner RNFLT on the left.

A decrease of FA at the putamen, caudate, anterior and posterior thalamic radiations, and anterior and posterior limbs of internal capsule was also demonstrated in this study. The thalamic nuclei (50–60 nuclei) project to ≥ 1 well-defined cortical area, by using the internal capsule, both the anterior and posterior limbs. This portion of the internal capsule is known as the thalamic radiation. The pulvinar, one of the lateral thalamic nuclei, is associated with visual function. Electrophysiologic studies have described visually responsive neurons with various properties within the pulvinar (direction,

Fig 3. Voxel-based DTI results for differences in the FA index between patients with POAG and disease-free control subjects. The results of the voxel-based DTI for differences in FA are superimposed on a common space (FMRIB58_FA). The color scale encodes areas of significant differences in the FA index between patients with POAG and the control subjects. Color represents regions of significantly decreased FA in patients with POAG.

color, and orientation selectivity).²⁷ Thus, the neurodegenerative changes observed in the present study may be related to glaucoma.

This study demonstrated volume changes in key areas of the visual system and FA decrease in structures playing a more peripheral role in vision. FA is a measure of directional dependence of diffusion and reflects fiber attenuation and coherence within a voxel, while MD reflects the magnitude of diffusion within a voxel.²⁸ Wallerian degeneration has been associated with a decrease in FA and a slight increase or lack of change in MD. The results of this study are indicative of brain tissue loss in the principal visual pathway and of a secondary degeneration in more extensive brain areas related to the visual system in patients with POAG.

This study had several limitations. First, the sample size was relatively small, limiting both statistical power and the ability to control for confounding variables. This small size might be the reason for the more pronounced left-sided degeneration observed, because POAG is often a bilateral condition. Second, histologic proof of the findings cannot be provided be-

cause this was a study involving human subjects. Third, the choice to require the subject to close his or her eyes during the examination may increase eye motion. Furthermore, a limitation of the VBM approach is the need for spatial smoothing and the problem of arbitrarily choosing the spatial smoothing extent. The interpretation of cross-subject differences in FA when the WM is mixed with significant amounts of GM is another problem. Another possible confound might be a within-scan head motion which can increase image blurring and bias FA. Finally, measuring FA values in regions where there are crossing tracts or tract junctions may be problematic, and an artificial lowering of FA value can occur at these junctions or crossing tracts.¹⁸

Conclusions

Patients with POAG present brain tissue loss in the visual pathway and secondary degenerative changes in many other brain areas related to the visual system. The atrophy in the deep GM structures may represent evidence of a possible link between glaucoma and more diffuse neurodegenerative dis-

ease. A variety of neuroprotective agents is currently under investigation, which may show promise for the treatment of glaucoma. In this context, VBM and DTI may be useful tools for identifying and monitoring neurodegenerative changes in patients with POAG. Further studies with a larger number of patients will be needed to confirm these observations.
