Associations between Measures of Structural Morphometry and Sensorimotor Performance in Individuals with Nonspecific Low Back Pain

K. Caeyenberghs, M. Pijnenburg, N. Goossens, L. Janssens, and S. Brumagne

ABSTRACT

BACKGROUND AND PURPOSE: To date, most structural brain imaging studies in individuals with nonspecific low back pain have evaluated volumetric changes. These alterations are particularly found in sensorimotor-related areas. Although it is suggested that specific measures, such as cortical surface area and cortical thickness, reflect different underlying neural architectures, the literature regarding these different measures in individuals with nonspecific low back pain is limited. Therefore, the current study was designed to investigate the association between the performance on a sensorimotor task, more specifically the sit-to-stand-to-sit task, and cortical surface area and cortical thickness in individuals with nonspecific low back pain and healthy controls.

MATERIALS AND METHODS: Seventeen individuals with nonspecific low back pain and 17 healthy controls were instructed to perform 5 consecutive sit-to-stand-to-sit movements as fast as possible. In addition, T1-weighted anatomic scans of the brain were acquired and analyzed with FreeSurfer.

RESULTS: Compared with healthy controls, individuals with nonspecific low back pain needed significantly more time to perform 5 sit-to-stand-to-sit movements ($P < .05$). Brain morphometric analyses revealed that cortical thickness of the ventrolateral prefrontal cortical regions was increased in patients with nonspecific low back pain compared with controls. Furthermore, decreased cortical thickness of the rostral anterior cingulate cortex was associated with lower sit-to-stand-to-sit performance on an unstable support surface in individuals with nonspecific low back pain and healthy controls ($r = -0.47, P < .007$). In addition, a positive correlation was found between perceived pain intensity and cortical thickness of the superior frontal gyrus ($r = 0.70, P < .002$) and the pars opercularis of the inferior ventrolateral prefrontal cortex ($r = 0.67, P < .004$). Hence, increased cortical thickness was associated with increased levels of pain intensity in individuals with nonspecific low back pain. No associations were found between cortical surface area and the pain characteristics in this group.

CONCLUSIONS: The current study suggests that cortical thickness may contribute to different aspects of sit-to-stand-to-sit performance and perceived pain intensity in individuals with nonspecific low back pain.

ABBREVIATIONS: DASS-21 = Depression Anxiety Stress Scale; NPRS = numeric pain rating scale; NSLBP = nonspecific low back pain; ODI = Oswestry Disability Index; STSTS = sit-to-stand-to-sit

Nonspecific low back pain (NSLBP) refers to low back pain that is not attributable to a specific cause. This category of low back pain disorders includes almost all low back pain symp-

toms.¹⁻³ Despite much effort in the development of treatment strategies for this large population,⁴ the effects of current NSLBP interventions are rather small. Therefore, understanding the underlying neural basis of NSLBP is crucial.

Previous imaging studies showed structural alterations in cortical and subcortical brain regions in individuals with NSLBP. However, mixed findings were obtained. Both increases and decreases in gray matter volume in different brain

regions were found in individuals with NSLBP compared with healthy controls. Volumetric alterations in individuals with NSLBP were observed, for example, in the dorsolateral prefrontal cortex,⁵⁻⁷ in the somatosensory cortex,^{6,8,9} in the temporal lobes,^{6,8} and in the thalamus.⁵⁻⁷ Together, most gray matter alterations in NSLBP, either reduced or increased, are observed in areas related to sensorimotor control. These alterations in sensorimotor-related areas are indicative of impaired sensorimotor performance, as observed in individuals with NSLBP with behavioral measures.¹⁰⁻¹² For example, individuals with NSLBP need notably more time to perform 5 consecutive sit-to-stand-to-sit (STSTS) movements compared with healthy controls.¹³ This STSTS task necessitates optimal sensorimotor control, which requires an efficient processing of sensory and motor information across the brain.¹⁴ However, nearly all structural brain imaging studies in NSLBP and in sensorimotor control have evaluated volumetric changes.⁵⁻⁹ Only 1 study in patients with Parkinson disease investigated how structural morphometry was associated with motor performance, showing an association between cortical thinning of the sensory parietotemporal areas and motor deficits.¹⁵ However, in NSLBP, cortical thickness and cortical surface area have been relatively understudied, while these 2 aspects of brain structure may be crucial to functional connectivity.

Cortical thickness and cortical surface area have a distinct genetic origin,^{16,17} a contrasting phylogeny,¹⁸ and different developmental trajectories.¹⁹ In addition, it is suggested that cortical thickness and cortical surface area reflect different aspects of the underlying neural architecture.²⁰ More specifically, cortical surface area is primarily determined by the number of columns within a cortical region, whereas cortical thickness is thought to reflect the number of cells within these cortical columns.^{18,21} Therefore, evaluation of cortical surface area and cortical thickness as separate measures can provide interesting additional knowledge on the neural mechanisms of NSLBP and sensorimotor tasks. These measures of structural morphometry can be computed by a surface-based analysis method called FreeSurfer (<http://surfer.nmr.mgh.harvard.edu>).²²

With the FreeSurfer analysis suite, 2 recent studies^{23,24} have provided evidence for alterations in cortical thickness in individuals with NSLBP compared with healthy controls. Although, Kong et al,²³ found increased cortical thickness in the bilateral primary somatosensory cortex, somatotopically associated with the lower back, in individuals with NSLBP, Dolman et al,²⁴ demonstrated that the differences in cortical thickness between individuals with NSLBP and healthy controls disappeared when controlling for age. Nevertheless, little research has been done on the associations with sensorimotor control and pain by using both surface area and cortical thickness. Therefore, this study was designed to investigate the distinct relation between the STSTS performance and the cortical surface area and cortical thickness in individuals with NSLBP and healthy controls. An association between cortical thinning of sensorimotor brain areas and a longer duration to perform 5 consecutive STSTS movements was hypothesized. This correlation analysis was performed to reveal the potential different contributions of the 2 nonvolumetric parameters to sensorimotor control. In addition, considering recent

findings,^{23,24} we hypothesized subtle cortical thinning in both sensorimotor- and pain-related brain regions in individuals with NSLBP compared with healthy controls.

MATERIALS AND METHODS

Participants

Thirty-four subjects were studied, including 17 subjects with NSLBP (11 women and 6 men) and 17 age-matched (± 2 years) healthy individuals (12 women and 5 men). Data from the same cohort were previously reported.^{25,26} Subjects with NSLBP were recruited consecutively from 2012 to 2013, as they responded to flyers in various settings (ie, academic [University Hospital Leuven] or community [sport clubs]), physician referrals (speciality care), mailings, and the Internet advertisements. Subjects with NSLBP were included under the following conditions: 1) they were between 20 and 50 years of age, 2) had experienced at least 6 months of disabling NSLBP (Oswestry Disability Index, Version 2 [adapted Dutch version, ODI-2]²⁷ of $>12\%$), 3) were not taking heavy opioids or drugs, 4) did not have vestibular and/or self-reported specific balance problems that precluded participation in the study procedure, 5) had no previous history of brain injury or other neurologic disorders, 6) had no neck problems (Neck Disability Index²⁸ of $<6\%$), 7) had no previous major trauma and/or operation of the spine or lower limbs, and 8) met the standard "MR safety" bench test criteria (eg, no claustrophobia, no metal implants in body). Six left-handed participants (2 patients with NSLBP and 4 healthy controls) were included in the study; however, the removal of left-handed participants did not change the results on group differences in structural morphometry and correlation analyses. All participants gave their written informed consent before the study. The study conformed to the principles of the Declaration of Helsinki (1964) and its later amendments; was approved by the local Ethics Committee of Biomedical Sciences, University Hospital Leuven, Belgium (s53802); and was registered at www.clinicaltrials.gov with the identification number NCT01540617.

Description of Measures

Pain Characteristics. The pain characteristics are defined by the numeric pain rating scale (NPRS) of the back, scores on the ODI-2, and the number of years of NSLBP. The NPRS back pain scores (0, no pain, to 10, worst pain) during the last month (NPRS_{back} usual) and at the moment of testing (NPRS_{back} current) were reported. These scores are well-validated measures to define the intensity of NSLBP.²⁹

Sit-to-Stand-to-Sit Task. The equipment, paradigm parameters, and dependent variables of the STSTS task were identical to those in previous studies.^{13,26} The participants were instructed to sit barefoot on a stool that was placed on a 6-channel force plate (Bertec, Columbus, Ohio) with their arms relaxed alongside their bodies and their vision occluded with nontransparent goggles. The stool height was adjusted for each participant to assure an angle of 90° in both hips and knees. After 15 seconds of usual sitting (no instructions on posture were given), participants were asked to perform 5 consecutive STSTS movements with a full range of motion as fast as possible. An investigator stood near the

participant to prevent actual falls. The force plate registered anteroposterior center-of-pressure displacements. The center-of-pressure displacements were sampled at 500 Hz by using a Micro1401 data acquisition system and Spike2 software (Cambridge Electronic Design, Cambridgeshire, UK). This protocol was performed with the feet placed on both a stable (force plate itself) and an unstable support surface (50-cm length $\times$ 41-cm width $\times$ 6-cm thickness [Balance Pad Elite; Airex, Sins, Switzerland], on the force plate). The total duration of the 5 consecutive STSTS movements was calculated on the basis of the anteroposterior center-of-pressure displacement. The starting- and end-points of the task were defined by the mean value of the center of pressure during usual sitting before and after the task. The STSTS task has shown good test-retest reliability (intraclass correlation coefficient = 0.84–0.94).^{30,31}

Depression Anxiety Stress Scale. Finally, a short version of the Depression Anxiety Stress Scale (DASS-21) was administered.³² This is a set of 3 self-report scales designed to measure the negative emotional states of depression, anxiety, and stress. Subjects are asked to use the 4-point severity/frequency scales to rate the extent to which they have experienced each state during the past week. Scores for depression, anxiety, and stress are calculated by summing the scores for the relevant items.

MR Imaging Acquisition and Analysis

MR images were acquired with a 3T Achieva scanner (Philips Healthcare, Best, the Netherlands) equipped with a 32-channel standard head coil. High-resolution whole-brain T1-weighted anatomic scans were obtained with a 3D turbo field echo sequence (voxel size = 0.98 $\times$ 0.98 $\times$ 1.2 mm³, TR = 9.59 ms, TE = 4.6 ms, flip angle = 8°, 182 coronal sections, FOV = 250 $\times$ 250 $\times$ 218 mm³, and matrix = 256 $\times$ 256 mm²). All T1-weighted anatomic scans were checked by a radiologist to assure that no brain lesions were present.

The structural images were analyzed with the FreeSurfer analysis suite, which is documented and freely available for downloading on-line. A technical description of the FreeSurfer procedures can be found in previous publications.^{33–42} The whole-brain analysis was performed with additional computing resources from the high-performance computing Tier1 cluster at the University of Ghent (<http://ugent.be/hpc/en>). The FreeSurfer analysis suite is a multistep procedure that consists of the following: 1) removal of nonbrain tissue by using a hybrid watershed/surface deformation procedure (skull stripping),⁴² 2) automated transformation to Talairach space, 3) subject-specific parcellation of the subcortical white matter and deep gray matter volumetric structures,^{36,43} and 4) calculation of cortical surface area and cortical thickness from all vertices within the 34 cortical parcellations per hemisphere.⁴⁴ Results of each subject were carefully visually inspected to ensure the accuracy of the skull stripping, segmentation, and cortical surface reconstruction. Where needed, the appropriate manual corrections were performed as explained by the FreeSurfer Tutorial (<http://surfer.nmr.mgh.harvard.edu/fswiki/FsTutorial>). In some datasets, it appeared that the skull strip left a lot of dura. However, it did not affect the surfaces following the gray and white matter borders. The averaged values across hemispheres were calculated and used in the statistical analysis to reduce the number of comparisons.

Table 1: Characteristics of the participants^a

Characteristic	NSLBP Group (n = 17)	Healthy Group (n = 17)	P Value
Age (yr)	33.3 $\pm$ 7.9	31.8 $\pm$ 8.2	.582
Sex (male/female)	6/11	5/12	.724
Height (cm)	173.0 $\pm$ 6.4	169.1 $\pm$ 6.4	.087
Weight (kg)	72.7 $\pm$ 10.6	64.9 $\pm$ 10.2	.036
BMI (kg/m ²)	24.2 $\pm$ 2.8	22.6 $\pm$ 2.7	.090
ODI-2	20.6 $\pm$ 7.6	0	NA
Years of NSLBP	9.8 $\pm$ 8.2	0	NA
NPRS _{back} usual	4.5 $\pm$ 2.0	0	NA
NPRS _{back} current	2.0 $\pm$ 2.0	0	NA

Note:—BMI indicates body mass index; NA, not applicable.

^a Data are presented as mean $\pm$ SD. Significance level is $P < .05$.

Statistical Analysis

Unpaired *t* tests were used to calculate group differences in characteristics of the participants. To determine whether an interaction effect of the Group $\times$ Support Surface was present in the STSTS performance, we performed a 2 $\times$ 2 repeated-measures ANOVA with Group as the between-subject factor (NSLBP group and healthy control group) and Support Surface as the within-subject factor (stable support surface and unstable support surface). The significance level for group differences in characteristics and STSTS performance was set at $P < .05$. MANCOVA was used to contrast cortical thickness and surface area measurements from each cortical parcellation by Group while controlling for age. The Bonferroni correction was applied to correct for multiple comparisons, resulting in an adjusted *P* value of $< .001$ (.05/34) for group differences in structural morphometry.

In addition, for each cortical parcellation from the morphologic measurement differences between groups, we also conducted post hoc power analyses by using G*Power, Version 3.1.9.2 (<http://www.softpedia.com/get/Science-CAD/G-Power.shtml>; with power [1- β] set at 0.80 and $\alpha = .05$, 2-tailed), to determine whether negative findings could be attributed to a limited sample size. The Outliers Labeling Rule (with a g-factor of 2.2)⁴⁵ was applied to detect outliers from both the STSTS data and the structural morphometry parameters. These values were excluded pair-wise from the correlation analysis. Relationships between STSTS performance and pain scores on one hand and the characteristics of morphometry on the other hand were examined by using partial (controlling for age) Spearman correlations across the total group and within each of the groups (individuals with NSLBP and healthy controls) in regions with significant group differences only. The *P* values reported for correlations were uncorrected for multiple comparisons with a statistical threshold of $P < .01$. These analyses, while showing a consistent trend, should be considered exploratory. The statistical analysis was performed with SPSS 22 (IBM, Armonk, New York).

RESULTS

Characteristics of the Participants

In accordance with the inclusion criteria, individuals with NSLBP reported scores above zero on the parameters of NSLBP-related disability and pain intensity (ODI-2, NPRS_{back} usual and NPRS_{back} current), whereas all healthy individuals scored zero on these parameters (Table 1). No significant differences in demographic characteristics were found between the in-

dividuals with NSLBP and healthy controls ($P > .05$), except for weight (NSLBP, 72.7 ± 10.6 kg; healthy controls, 64.9 ± 10.2 kg; $P = .036$) (Table 1). According to the cutoff scores of the DASS-21, 3 individuals with NSLBP showed moderate-to-severe depression, 4 individuals with NSLBP showed moderate-to-severe anxiety, and 5 individuals with NSLBP showed moderate-to-severe stress, whereas all controls scored zero on the 3 scales of the DASS-21.

Sit-to-Stand-to-Sit Task

A significant main effect of the factors Group ($F = 11.348$, $P = .002$) and Surface ($F = 6.29$, $P = .017$) was observed in the duration of performing 5 consecutive STSTS movements. More specifically, individuals with NSLBP needed significantly more time to perform the STSTS task on stable and unstable support surfaces (stable, 18.1 ± 6.9 seconds; unstable, 16.8 ± 5.9 seconds) compared with healthy controls (stable, 12.9 ± 2.5 seconds; unstable, 11.5 ± 2.0 seconds) ($P = .002$). Moreover, a significant decrease in the duration of the STSTS task was found on unstable support surfaces compared with the stable conditions, irrespective of Group ($P = .017$). No interaction effect between the factors Group and Surface was present ($P > .05$).

Contribution of Weight

Because a significant difference in weight was found between subjects with NSLBP and healthy controls, post hoc correlation anal-

yses were performed to determine whether weight was associated with pain scores, structural morphometry measures, and STSTS performance. Our results revealed a significant positive correlation between the number of episodes of NSLBP and weight ($r = 0.357$, $P = .038$). No significant correlations between weight and the other measures of pain could be demonstrated (Table 2). Also, the weight of the participants was not significantly correlated with the total time needed to perform the STSTS task on stable and unstable support surfaces or with the structural morphometry ($P > .05$). Therefore, weight was not included in the subsequent analysis.

Structural Morphometry

MANCOVA of the cortical parcellations between subjects with NSLBP and healthy controls (On-line Tables 1 and 2 and Fig 1), including age as a covariate in the model, showed cortical thickening in the individuals with NSLBP in the pars opercularis and pars triangularis of the inferior ventrolateral prefrontal cortex ($P < .001$). These brain regions did retain significance after correcting for multiple comparisons. Using a less stringent threshold of $P < .01$ (indicated by footnote *a* in On-line Table 1), we observed a cortical thickening trend in the NSLBP group in the cuneus ($P < .003$), fusiform gyrus ($P < .004$), inferior parietal gyrus ($P < .002$), lateral orbitofrontal cortex ($P < .004$), posterior cingulate gyrus ($P < .008$), superior frontal gyrus ($P < .01$), superior temporal gyrus ($P < .006$), and transverse temporal gyrus ($P < .004$) and a cortical thinning trend in the rostral anterior cingulate gyrus ($P < .009$) and the insula ($P < .002$).

Within these regions, we checked for correlations to depression, anxiety, and stress (as measured by the DASS-21) to exclude the possibility that the significant group differences in cortical thickness may be explained by differences in emotional states. Only 1 significant positive correlation within the patient group

Table 2: Relationships between weight and measures of pain

Measure of Pain	Spearman Correlation Coefficient	P Value
NPRS _{back} usual	0.314	.071
NPRS _{back} current	0.323	.630
Years of NSLBP	0.303	.082
No. of episodes of NSLBP	0.357	.038

FIG 1. Significant group differences (after correcting for age) in cortical thickness.

FIG 2. Scatterplots indicating the relationship between cortical thickness and STSTS performance and the pain-intensity score.

between the Depression Scale and cortical thickness was observed for the superior temporal gyrus ($r = 0.66$, $P < .007$).

No significant differences in cortical surface area between individuals with NSLBP and healthy controls could be demonstrated ($P > .001$, On-line Table 2). On-line Table 2 also shows the sample sizes required to find statistically significant differences in surface area between the groups for each cortical parcellation. The numbers needed per group ranged from 41 to 29,790. These results show that sample size would have to increase up to at least 41 for surface area measurements for group differences to reach statistical significance at the .05 level. Thus, it is likely that our negative findings for surface area can be attributed to a limited sample size.

Association between Cortical Thickness and the Sit-to-Stand-to-Sit Performance

Relationships (corrected for age) between STSTS performance and cortical thickness were investigated in regions with significant group effects. The duration to perform 5 consecutive STSTS movements on an unstable support surface was negatively correlated with the cortical thickness of the rostral anterior cingulate ($r = -0.47$, $P < .007$) within the total group (Fig 2). In other words, decreased cortical thickness of the rostral anterior cingulate cortex was associated with a longer duration of the STSTS task on an unstable support surface (lower performance). To some extent, this correlation coefficient between cortical thickness and STSTS performance was valid only for the NSLBP group ($r = -0.51$, $P = .055$).

Association between Structural Morphometry and Pain Characteristics

Within the group of individuals with NSLBP, significant positive correlations (as shown in Fig 2) were found between the NPRS

back pain score (indexed by the NPRS_{back} usual) and the cortical thickness of the superior frontal gyrus ($r = 0.70$, $P < .002$) and the pars opercularis of the inferior ventrolateral prefrontal cortex ($r = 0.67$, $P < .004$). In other words, increased cortical thickness of the superior frontal gyrus and pars opercularis of the inferior ventrolateral prefrontal cortex was associated with an increased level of pain intensity in the individuals with NSLBP. No significant correlations were found between cortical surface area and the pain characteristics in this group of individuals with NSLBP.

DISCUSSION

This study is the first one correlating structural morphometrics with STSTS performance in patients with chronic pain, more specifically NSLBP. Brain morphometric analyses revealed that cortical thickness of the ventrolateral prefrontal cortical regions was increased in patients with NSLBP compared with controls. This increased cortical thickness was positively correlated with increased pain scores in the NSLBP group. Our behavioral results showed that individuals with NSLBP needed significantly more time to perform 5 consecutive STSTS movements on stable and unstable support surfaces. In addition, decreased cortical thickness of the rostral anterior cingulate cortex was associated with lower STSTS performance on unstable support surfaces.

Increased Cortical Thickness in Ventrolateral Prefrontal Cortical Regions: Association with Pain Intensity

Numerous studies with voxel-based morphometry have examined alterations of gray matter densities within specific brain regions in chronic pain conditions (for meta-analyses, see Pan et al,⁴⁶ and Smallwood et al).⁴⁷ However, surface-based features, such as cortical thickness and surface area, are more direct mea-

asures of cortical morphometry than the gray matter density values used in voxel-based morphometry.^{34,48} To our knowledge, no study to date has examined these 2 measures in a group of individuals with chronic pain. So far, only 2 studies have investigated cortical thickness in individuals with NSLBP by using the FreeSurfer analysis suite. One study demonstrated an increased cortical thickness of the primary somatosensory cortex, more specifically the area somatotopically representing the lower back.²³ In another study, group comparisons revealed cortical thickening in the right rostral middle frontal gyrus and a trend toward cortical thickening in the right paracentral lobule in patients with chronic low back pain. These regions did not retain significance after correcting for age. These previous findings of cortical thickening comport with our results. Our analyses, after correcting for age, revealed cortical thickening in individuals with NSLBP in the pars opercularis and pars triangularis, which together form the midportion of the ventrolateral prefrontal cortex. The changes identified in the ventrolateral prefrontal cortical regions in our group of subjects with NSLBP have face validity—that is, these brain regions appear to play an important role in the cognitive regulation of pain and emotion.^{49,50} Several voxel-based morphometry studies have identified changes in the ventrolateral prefrontal cortex in patients with other chronic pain conditions, such as migraine.^{51,52} Experimental pain studies with functional imaging techniques have also demonstrated altered activation of the same brain regions.⁵³

The ventrolateral prefrontal cortex has also been reported to be involved in patients with anxiety, depressive symptoms, or stress.^{54,55} However, with the DASS-21, we checked whether the group results could be explained by depression, anxiety, or stress. We found only 1 significant positive correlation between cortical thickness of the superior temporal gyrus and the depression scale score. The present results convincingly show the important involvement of the ventrolateral prefrontal regions in pain processing. We have also found changes in cortical thickness in other structures known to be associated with pain processing and modulation, including the orbitofrontal regions, cingulate cortex, insula, and inferior parietal lobule. However, these regions did not survive Bonferroni correction.

Moreover, our results revealed that the pattern of specific alterations in brain morphology was directly related to the intensity of pain (ie, the increase in cortical thickness of the pars opercularis of the inferior frontal gyrus corresponded to greater pain). Correlation analyses revealed that increased cortical thickness was related to higher pain intensity scores in the NSLBP group. Our results are consistent with those in a previous study of Schmidt-Wilcke et al, 2006,⁶ in patients with chronic back pain in which brain regions showing an increase in gray matter density (such as the left thalamus and left putamen) coincided with increasing pain intensity.

Our findings of the relation between increased cortical thickness and increased pain scores in patients with NSLBP may reflect the consequence of a reorganization process of brain regions involved in a disproportionate number of signals of pain, emotion, and cognition. It can be suggested that this increased cortical thickness of the ventrolateral prefrontal cortex can eventually be normalized by specific and targeted training.⁵⁶ Limited evidence

available in the literature^{57,58} shows that treating chronic pain with cognitive behavioral therapy can lead to alterations in prefrontal brain regions and that the changes in these prefrontal regions correlate with clinical improvement. Whether morphologic changes can be normalized needs to be addressed in further research.

Decreased Cortical Thickness in the Rostral Anterior Cingulate Cortex: Relationship with Sensorimotor Performance

The changes in morphology correlated not only with pain scores but also with functional changes in sensorimotor control. Our behavioral results revealed that the NSLBP group required significantly more time to perform the STSTS task on both stable and unstable support surfaces compared with the healthy controls. This result is in agreement with previous studies.^{13,26} The STSTS task on an unstable support surface is ultimately challenging the sensorimotor system (including the proprioceptive system) because this condition requires additional reweighting of the proprioceptive signals due to the decreased reliability of proprioceptive signals from the ankle region.⁵⁹ Proprioception can be defined as “the unconscious perception of movement and spatial orientation arising from stimuli within the body,”⁶⁰ and the unstable support surface forces the central nervous system to down-weight the less reliable ankle muscle proprioception and consequently to up-weight the proprioceptive input from more proximal segments, to provide optimal postural control.^{59,61} Nevertheless, a faster performance on an unstable support surface compared with the stable condition was observed. Because of the nonrandomized order of these conditions, this is possibly due to a learning effect. Despite this limitation, the individuals with NSLBP needed more time to perform 5 consecutive STSTS movements compared with controls, in both conditions.

This finding fits with previous ones.¹³ The decreased performance on a sensorimotor task in individuals with NSLBP, as represented by the increased duration of the STSTS task, fits within the findings of previous studies showing impaired sensorimotor control in individuals with NSLBP.^{10,62} Indeed, the STSTS task requires optimal sensorimotor control, for example, in terms of postural control.⁶³ Recently, an association was observed between the proprioceptive reweighting capacity and microstructural integrity of the superior cerebellar peduncle in individuals with NSLBP. This finding suggests a neural basis for sensorimotor impairments.²⁵ In this current study, the association between the sensorimotor STSTS task and structural morphometry in terms of cortical surface area and cortical thickness in individuals with NSLBP and healthy controls was investigated. Evaluation of these nonvolumetric parameters as separate measures, reflecting different aspects of the underlying neural architecture, is important in investigating what drives sensorimotor tasks.

In the present study, decreased cortical thickness of the rostral anterior cingulate cortex was associated with lower STSTS performance on unstable support surfaces. This correlation was significant within the total group, and a trend within the group of the patients with NSLBP was found. The anterior cingulate cortex is considered part of the general pain matrix^{64,65} and has been im-

plicated in anticipation of pain and affective processing of pain.⁶⁶ Structural alterations in the anterior cingulate cortex have been reported in a wide range of chronic pain conditions.^{46,47} The anterior cingulate cortex is also the brain region that most consistently shows activation in response to acute pain stimuli.⁶⁶ To our knowledge, this is the first time that an association between the cortical thickness of the anterior cingulate cortex and performance on a sensorimotor task in individuals with NSLBP and healthy controls has been observed.

Of note, our statistical analyses (group comparisons and correlation analyses) revealed only significance for cortical thickness. In light of the radial unit hypothesis,^{18,67} our significant cortical thickness findings may reflect abnormalities in the number or size of the neuronal cell bodies within the cortical mini-columns of the ventrolateral prefrontal cortical regions in patients with NSLBP. In contrast, the absence of cortical surface area findings does not support individuals with NSLBP possibly having abnormal proliferation or decline in the number of cortical minicolumns. However, the power of our study was probably not enough to detect a significant group difference in surface area. While our sample size was similar to that in prior studies investigating differences in brain structure in patients with chronic pain,^{46,47} we also performed post hoc power analyses to determine whether negative findings for surface area could be attributed to the low sample size. We demonstrated that for most cortical parcellations, at least 41 subjects were required per group to observe significant differences in surface area. To precisely interpret these findings with respect to their functional significance, further research addressing the relationship between cerebral micro- and macrostructures as well as brain function is clearly necessary.

Limitations

The main shortcoming of our study was the small sample size, especially for the numerous correlations performed from the FreeSurfer output. Replication of the present morphologic findings with a larger sample is warranted. Moreover, future studies in a large number of participants should also stratify the groups by age rather than controlling for age in the statistical analyses. Another limitation of the present study pertains to the correlative nature of our study. The correlation coefficients computed between pain scores and brain morphometry provided us information about the nature of the relations between these variables but did not allow tests of strong causal inference. To achieve the latter, a longitudinal study is necessary. Finally, the inclusion of other dynamic sensorimotor tasks, such as gait, could further clarify the different aspects of sensorimotor control.

CONCLUSIONS

In the present study, patients with NSLBP showed alterations of cortical thickness in brain regions that play an important role in the cognitive regulation of pain, as well as an impaired STSTS performance compared with healthy controls. Cortical thickening was associated with increased pain intensity in the individuals with NSLBP. In addition, decreased cortical thickness of the rostral anterior cingulate cortex was correlated with lower STSTS performance on an unstable support surface. These findings

suggest that in addition to measures of volume, cortical thickness may provide a more complete understanding of the central basis of sensorimotor tasks, more specifically in the NSLBP population.

ACKNOWLEDGMENTS

The authors are grateful to the study volunteers for their participation.
