Cerebral Venous Thrombosis Associated with COVID-19

ABSTRACT

SUMMARY: Despite the severity of coronavirus disease 2019 (COVID-19) being more frequently related to acute respiratory distress syndrome and acute cardiac and renal injuries, thromboembolic events have been increasingly reported. We report a unique series of young patients with COVID-19 presenting with cerebral venous system thrombosis. Three patients younger than 41 years of age with confirmed Severe Acute Respiratory Syndrome coronavirus 2 (SARS-CoV-2) infection had neurologic findings related to cerebral venous thrombosis. They were admitted during the short period of 10 days between March and April 2020 and were managed in an academic institution in a large city. One patient had thrombosis in both the superficial and deep systems; another had involvement of the straight sinus, vein of Galen, and internal cerebral veins; and a third patient had thrombosis of the deep medullary veins. Two patients presented with hemorrhagic venous infarcts. The median time from COVID-19 symptoms to a thrombotic event was 7 days (range, 2–7 days). One patient was diagnosed with new-onset diabetic ketoacidosis, and another one used oral contraceptive pills. Two patients were managed with both hydroxychloroquine and azithromycin; one was treated with lopinavir-ritonavir. All patients had a fatal outcome. Severe and potentially fatal deep cerebral thrombosis may complicate the initial clinical presentation of COVID-19. We urge awareness of this atypical manifestation.

ABBREVIATIONS: COVID-19 = coronavirus disease 2019; CVT = cerebral venous thrombosis; RT-PCR = real-time reverse transcriptase polymerase chain reaction; SARS-CoV2 = Severe Acute Respiratory Syndrome-coronavirus 2

A novel Severe Acute Respiratory Syndrome-coronavirus 2 (SARS-CoV2) was identified on January 7, 2020, by the Chinese Center for Disease Control and Prevention from a nasopharyngeal swab in a patient with atypical pneumonia in Wuhan, Hubei province, China.1 The mortality rate of critically ill patients with COVID-19 is high. As of May 13, 2020, more than 1.4 million individuals had tested positive for the SARS-CoV2 in the United States, leading to >84,000 deaths. Acute cardiac injury, acute kidney injury, and precipitous thromboembolic events have been increasingly reported and may develop irrespective of pulmonary or respiratory symptoms at presentation.1–5

Recent studies have reported the potential development of a hypercoagulable state in COVID-19.2,3,6,7 Viral infections may promote dysfunction of endothelial cells, leading to excess thrombin generation and inhibition of fibrinolysis.8–10 Moreover, hypoxemia is associated with an elevation of blood viscosity and activation of hypoxia-related genes that mediate coagulation and fibrinolysis, favoring thrombotic events.11,12 This septic-like coagulopathy additionally may lead to venous thrombosis, pulmonary embolism, and ultimately disseminated intravascular coagulation.3,4 Cerebral venous thrombosis, in particular, can present with a broad variety of neurologic signs and symptoms.13,14 We report herein 3 independent cases of patients with COVID-19 who presented with stroke due to cerebral venous thrombosis and had uniformly fatal outcomes.

MATERIALS AND METHODS

We report 3 independent cases of patients presenting to a single academic hospital system in the initial weeks of the COVID-19 surge during a 10-day period. The 3 patients composing our initial experience developed profound neurologic injury secondary to cerebral venous thrombosis (CVT), with SARS-CoV-2 infection confirmed by real-time reverse transcriptase polymerase chain reaction (RT-PCR) assay. The mean age was 34 years (range, 23–41 years; 2 men and 1 woman). All patients presented during 10 days beginning in March 2020. The study was approved by the institutional review board. Medical charts were...
reviewed for significant history, physical examination findings, laboratory findings, and imaging. Due to the retrospective nature of this report, informed consent was not required. We used the Case Report Guideline (CARE; https://www.care-statement.org/) checklist when writing this report.15

RESULTS
Case 1
A 38-year-old man with mild autism spectrum disorder was admitted to the emergency department with vomiting and diarrhea for 10 days, headache for the past 7 days, and altered mental status for the past 2 days. At presentation, he exhibited signs of dehydration, blood pressure of 127/62 mm Hg, and temperature of 102.9°F. He was screened by nasopharyngeal swab with an RT-PCR for SARS-CoV-2, with positive findings. Chest radiograph and CT confirmed patchy multifocal peripheral and peribronchovascular air space opacities (a combination of ground-glass and consolidation) in all lobes (Fig 1A).

Head CT revealed hyperdensity in the straight sinus, distal superior sagittal sinus, torcular, and right transverse sinus, as well as in several cortical veins adjacent to the superior sagittal sinus, a pattern consistent with CVT (Fig 1B). There was associated cerebral edema. Pertinent laboratory results are listed in the Table. CT venography confirmed CVT, including a near-occlusive thrombus in the right internal cerebral vein (Fig 1C). Enoxaparin, 70 mg, was given subcutaneously twice a day. Nevertheless, the patient rapidly decompensated, with extensor posturing of the arms and clonus. Cranial nerve examination findings were normal; the NIHSS score was 14. The patient’s temperature increased to 104.3°F, his respiratory rate increased to 40 breaths per minute, and he quickly became hypoxemic, gasping for air, and was intubated 7 hours after admission.

The patient was subsequently taken to the angiography suite for a percutaneous venous mechanical thrombectomy. Arterial injections showed decreased contrast transit time throughout the brain parenchyma, indirectly suggesting significantly increased supra- and infratentorial pressures (Fig 1D). Marked venous congestion of the right hemisphere, with similar-but-lesser involvement on the left due to partial patency of the sigmoid sinus and the associated vein of Labbé, and congestion of the vein of Galen, internal cerebral system, and posterior fossa were present.

Thrombectomy was performed using our standard procedures with satisfactory results in the superficial venous system (Fig 2A–2C) but residual cortical vein thrombi as shown in Fig 2D. A microcatheter was left in the superior sagittal sinus with an infusion rate of 2 mg/h of tPA. No neurosurgical intervention was advised at that point. The patient was treated with lopinavir-ritonavir and had an initial improvement on neurologic examination in the following 6 hours; however, his respiratory status soon deteriorated, leading to cardiac arrest and death 32 hours after admission.

Case 2
An otherwise healthy 41-year-old woman, recently discharged from an outside hospital following a short and uneventful admission for COVID-19, presented to our emergency department with confusion and a sudden episode of aphasia. She had received hydroxychloroquine and azithromycin, started during her first

FIG 1. Acute onset of cerebral venous thrombosis in multiple locations in a man with COVID-19 without any significant comorbidities except for mild autism spectrum disorder and Tourette syndrome. A, Axial view of a CT of the chest shows patchy multifocal peripheral and peribronchovascular airspace opacities with a combination of ground-glass and consolidation in different lobes. B, Axial view, CT of the head without contrast, shows effacement of the cerebral sulci suggestive of significant cerebral edema; hyperdensity is seen in the region of the superior sagittal sinus posteriorly (arrow), characteristic of dural venous thrombosis. C, CVT with sagittal reconstruction demonstrates extensive occlusive filling thrombus within the superior sagittal (white arrow), right transverse, and sigmoid sinuses; thrombosis extends from the torcula into the straight sinus (black arrow). There is occlusion of several cortical veins adjacent to the superior sagittal sinus as well. D, Digital subtraction angiography, lateral view, reveals significant venous congestion involving the entire right cerebral hemisphere with no visualization of the superior sagittal (white arrow), transverse, and sigmoid sinuses, with clot extension in the straight sinus (black arrow).
admission. Home medications included estrogen-containing oral contraceptives. Her blood pressure was 107/75 mm Hg, and she was afebrile. The patient had global aphasia and left-gaze preference with an NIHSS score of 16. Initial head CT findings were normal. Intravenous tPA was not given because last her known well time was \( >4.5 \) hours. CT angiography did not identify any large-vessel occlusion. There was right-greater-than-left multifocal consolidation throughout the lungs on chest imaging.

While waiting for a brain MR imaging, she developed labored breathing, a further decrease in the level of consciousness, and worsened neurologic examination findings with extensor posturing to noxious stimulation; she was then intubated and sedated. The CSF analysis revealed elevated protein levels (616 mg/dL), 41 white blood cells/mm\(^3\) with polymorphonuclear predominance (84%), and a normal glucose level. A multiplex PCR assay was negative for common pathogens causing meningitis and encephalitis. A repeat head CT showed interval development of a venous infarction in the left basal ganglia, thalamus, and mesial temporal lobe with hemorrhagic transformation, intraventricular hemorrhage, and obstructive hydrocephalus (Fig 3A–B). A chest CT was characteristic for COVID-19 (Fig 3C). A CT venogram confirmed occlusion of the internal cerebral veins with significantly reduced enhancement of the vein of Galen and distal straight sinus (Fig 3D). Concomitantly, her D-dimer level increased from 787 to 2032 ng/mL; it had been 243 ng/mL 7 days prior. An external ventricular drain was placed. Heparin infusion was initiated without a bolus in the treatment of deep CVT. The patient soon exhibited loss of brain stem reflexes and died 4 days from presentation.

**Case 3**

A 23-year-old man with no known medical history presented with lethargy in the setting of 1 week of headaches, body aches, fever, and dry cough. Blood pressure at presentation was 95/53 mm Hg. Multifocal pneumonia was present on the initial chest x-ray. RT-PCR was positive for SARS-CoV-2. A head CT was ordered due to the decreased level of consciousness and revealed patchy areas of low density in the bilateral cerebral hemispheres with foci of subcortical hemorrhage in the left parieto-occipital region. A
Atheroembolic infarctions or deep MCA borderline ischemia. Acute and absence of large-vessel occlusion disfavored the diagnosis of manifestations of a generalized vasculopathy such as scans, the imaging appearance was thought to be consistent with intensity of the white matter on long-echo T2- and T2*-weighted unsupported by the history. In combination with generalized low sense of deep ganglia injury, and toxic-metabolic etiologies were necrotizing leukoencephalitis was considered unlikely in the ab-

We report an unusual presentation characterized by catastrophic cerebral venous thrombosis in young, previously healthy patients, infected with SARS CoV 2, previously healthy and potentially without antecedent cardiopulmonary symptoms or fever. Although dehydration was a precipitating factor in cases 1 and 3, and, oral contraceptives, a risk factor in case 2, COVID-19 was probably an additive risk factor in this series.

The superior sagittal sinus is the more frequently reported cerebral venous structure involved (63% of patients in a large MR imaging series); however, more extensive multi-site thrombosis is the typical finding. The deep venous system is an independent predictor of death in the International Study on Cerebral Vein and Dural Sinus Thrombosis (odds ratio, 8.5; 95% confidence interval, 2.6–27.8).13,14 Most reports included children, especially neonates.

**Hypercoagulable State in Other Scenarios**

Numerous factors are related to CVT, including the use of oral contraceptives, pregnancy, and puerperium, which produce occur in disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and related thrombotic microangiopathies, including compromise of the deep medullary veins.16,17 Common to the preceding processes is endothelial dysfunction and impaired thromboresistance, which have been reported extensively in COVID-19 and other SARS-mediated disorders.18

In the ensuing days, the patient further deteriorated, with D-dimer levels increasing from earlier values of 1625 ng/mL to >11,000 ng/mL the day he died and ferritin values reaching 18,431 ng/mL. The patient was intubated following worsening hypotension and fulminant acute respiratory distress syndrome in the following days before his death.

**DISCUSSION**

CTA of the head had negative findings; however, there remained concern for CVT. The initial laboratory work-up further established a new diagnosis of diabetic ketoacidosis with new-onset diabetes mellitus (glucose level = 1384 mg/dL and pH = 7.0). Azithromycin and hydroxychloroquine were both administered.

A subsequent brain MR imaging (Fig 4) revealed confluent, nonenhancing regions of pathologically reduced diffusion throughout the subcortical and deep hemispheric white matter bilaterally, left greater than right. Punctate foci of susceptibility artifacts consistent with petechial hemorrhage were revealed on gradient recalled-echo images. Differential considerations included potential complications of diabetic ketoacidosis, which can include arterial and venous compromise together with secondary injury by increased intracranial pressure, and posterior reversible encephalopathy syndrome–like white matter injury. The imaging pattern and absence of large-vessel occlusion disfavored the diagnosis of atheroembolic infarctions or deep MCA borderline ischemia. Acute necrotizing leukoencephalitis was considered unlikely in the absence of deep ganglia injury, and toxic-metabolic etiologies were unsupported by the history. In combination with generalized low intensity of the white matter on long-echo T2- and T2*-weighted images, the imaging appearance was thought to be consistent with manifestations of a generalized vaso-occlusive crisis such as can

![FIG 3. Subacute onset of isolated deep cerebral venous thrombosis in a patient with COVID-19. A, Noncontrast head CT, axial view, reveals an infarct of the left basal ganglia and thalamus, with hemorrhagic transformation and intraventricular hemorrhage with obstructive hydrocephalus. B, Noncontrast head CT, sagittal reconstruction, reveals hyperdensity in the topography of the vein of Galen (short arrow) and left internal cerebral vein (long arrow), corresponding to deep venous thrombosis. C, CT of the chest, axial view, demonstrates patchy multifocal airspace opacities combining ground-glass and consolidation in different lobes, suggestive of pneumonia/pneumonitis. D, CT venogram, MPR sagittal reconstruction, shows a filling defect in the vein of Galen (short arrow), internal cerebral veins (long arrow), and the anterior aspect of the inferior sagittal sinus, confirming deep venous thrombosis.](https://www.ajnr.org)
transient prothrombotic states.\textsuperscript{19,25} CVT accounts for 2\% of pregnancy-associated strokes.\textsuperscript{26} Diabetes mellitus, systemic inflammatory disease, cancer, hematologic disorders, head and neck infections, and CNS infections and hyperhomocysteinemia are other significant causes, and the patients were not systematically worked up for all those conditions.\textsuperscript{11,12,27,28} Anemia is another known risk factor for CVT, though not present in our patients.\textsuperscript{29}

Numerous viral infections are associated with coagulopathy.\textsuperscript{8-10,30-32} Direct or indirect activation of endothelial cells by viruses may impair coagulation and the fibrinolytic systems. Moreover, antiphospholipid antibodies can be identified in several viral infections, including cytomegalovirus, HIV, and varicella zoster virus,\textsuperscript{8-10} also in immunocompetent patients.\textsuperscript{9} A hypercoagulable state is well-known among patients with human herpes viruses (DNA viruses) and HIV.\textsuperscript{8-10,30,32} Chronic HIV infection has been associated with up to a 10-fold increased risk of venous thrombosis.\textsuperscript{8}

Finally, microvascular thrombosis was seen in a specific transgenic mouse model, used in studying the Middle East respiratory syndrome coronavirus infection.\textsuperscript{31}

\textbf{Hypercoagulable State in COVID-19}

A recent study comparing a cohort of 94 patients with SARS-CoV-2 infection in a hospital in Wuhan with 40 healthy volunteers found values of D-dimer, fibrin/fibrinogen-degradation products, and fibrinogen to be significantly higher among patients with COVID-19.\textsuperscript{6}

In reporting a 21.6\% incidence of deep venous thrombosis in 88 laboratory-confirmed cases in Wuhan,\textsuperscript{33} Wang et al\textsuperscript{3} observed positive correlations between the degree of D-dimer elevation and the incidence of deep venous thrombosis with the severity of disease, possibly related to overwhelming endothelial cell activation.\textsuperscript{3,34} Indeed, D-dimer levels were >500 ng/mL in all patients in this report at diagnosis, being >55,000 ng/mL in case 1.

There is also a growing understanding that antiphospholipid antibodies (anticardiolipin immunoglobulin A, and anti–β2-glycoprotein I immunoglobulin A and immunoglobulin G) may play a role in both arterial and venous infarcts. Zhang et al\textsuperscript{3} found positive antiphospholipid antibodies in 3 patients with critical COVID-19 and multifocal ischemic strokes.

Yang et al\textsuperscript{34} reported a high prevalence of hypertension, diabetes, and respiratory system disease in a meta-analysis including 46,248 patients with severe presentation of COVID-19, some with well-known risk factors for venous thromboembolism.\textsuperscript{35} Moreover, increased immobility of vulnerable and at-risk patients may occur during resource-strained pandemics, with shortages of health care personnel further contributing to conditions of venous stasis and thromboembolism.\textsuperscript{12} More studies are needed to clarify the direct relationship of the SARS-CoV-2 and thromboembolic disease.

\textbf{Cerebrovascular Disease in Patients with COVID-19}

Recently, Li et al\textsuperscript{2} identified 13 patients (5.9\%) with stroke among 221 consecutive patients with confirmed SARS-CoV-2 infection in Wuhan. Among this cohort, 11 had severe disease while only one, a 32-year-old man, had CVT involving multiple cortical veins. Parenthetically, a surge in large-vessel arterial occlusive strokes was reported in a group of patients younger than 50 years of age in New York City.\textsuperscript{36}

In general, approximately 80\% of patients with CVT experience acute-to-subacute onset of symptoms.\textsuperscript{3} The median time from onset to diagnosis of the thrombotic events was 7 days, the same as reported in the literature. Although headache is the most commonly reported initial symptom; altered consciousness was the critical symptom in each of the present cases. When a patient is admitted to the hospital with headache, altered mental status, focal neurologic deficits, and seizures, the likelihood of an earlier diagnosis is higher.\textsuperscript{13} Early identification is critical because prompt anticoagulation and/ or endovascular management may decrease the progression of cerebral edema, intracranial pressure, and hemorrhage rates, improving outcomes.
COVID-19 disease spectrum is encouraged. Increased fatality of the disease. Heightened awareness of COVID-19 is a serious contributor to hypercoagulopathy on case 3.

Limitations
The main limitation is that this is a small case series of only 3 patients collected in a short time. Also, 2 patients were treated with azithromycin and hydroxychloroquine before their CVTs, and the effects of these drugs during COVID-19 infection are under study and inconclusive at this time. Both may affect coagulation and interact with other medications and treatment, and it is unknown whether they could have been contributors to the CVTs. Moreover, there were concomitant signs of dehydration in the first case, and the second patient was on oral contraceptive pills, both known precipitating or risk factors for CVT. Another limitation of this work is the lack of a strongly confirmed diagnosis on case 3.

CONCLUSIONS
An unusual presentation with catastrophic cerebral venous thrombosis in previously healthy young patients infected with SARS-CoV-2 was demonstrated. No conclusions can be drawn other than that these cases provide hints as to the accumulating evidence that COVID-19 is a serious contributor to hypercoagulation, increasing the fatality of the disease. Heightened awareness of this atypical but potentially treatable complication of the COVID-19 disease spectrum is encouraged.
