ABSTRACT

BACKGROUND AND PURPOSE: Intraplaque hemorrhage contributes to lipid core enlargement and plaque progression, leading to plaque destabilization and stroke. The mechanisms that contribute to the development of intraplaque hemorrhage are not completely understood. A higher incidence of intraplaque hemorrhage and thin/ruptured fibrous cap (upstream of the maximum stenosis in patients with severe [$\geq 70\%$] carotid stenosis) has been reported. We aimed to noninvasively study the distribution of intraplaque hemorrhage and a thin/ruptured fibrous cap in patients with mild-to-moderate carotid stenosis.

MATERIALS AND METHODS: Eighty-eight symptomatic patients with stroke ($<70\%$ carotid stenosis included in the Plaque at Risk study) demonstrated intraplaque hemorrhage on MR imaging in the carotid artery plaque ipsilateral to the side of TIA/stroke. The intraplaque hemorrhage area percentage was calculated. A thin/ruptured fibrous cap was scored by comparing pre- and postcontrast black-blood TSE images. Differences in mean intraplaque hemorrhage percentages between the proximal and distal regions were compared using a paired-samples *t* test. The McNemar test was used to reveal differences in proportions of a thin/ruptured fibrous cap.

RESULTS: We found significantly larger areas of intraplaque hemorrhage in the proximal part of the plaque at 2, 4, and 6 mm from the maximal luminal narrowing, respectively: 14.4% versus 9.6% ($P = .04$), 14.7% versus 5.4% ($P < .001$), and 11.1% versus 2.2% ($P = .001$). Additionally, we found an increased proximal prevalence of a thin/ruptured fibrous cap on MR imaging at 2, 4, 6, and 8 mm from the MR imaging section with the maximal luminal narrowing, respectively: 33.7% versus 18.1%, $P = .007$; 36.1% versus 7.2%, $P < .001$; 33.7% versus 2.4%, $P = .001$; and 30.1% versus 3.6%, $P = .022$.

CONCLUSIONS: We demonstrated that intraplaque hemorrhage and a thin/ruptured fibrous cap are more prevalent on the proximal side of the plaque compared with the distal side in patients with mild-to-moderate carotid stenosis.

ABBREVIATIONS: FC = fibrous cap; IPH = intraplaque hemorrhage; QIR TSE = quadruple inversion recovery turbo spin-echo; TRFC = thin/ruptured fibrous cap

Rupture of a vulnerable atherosclerotic plaque is an important underlying cause of myocardial infarction and stroke.¹ Noninvasive visualization of plaque vulnerability has demonstrated that intraplaque hemorrhage (IPH) contributes to enlargement of the lipid core and plaque progression, leading to plaque destabilization.^{2,3} Indeed, we and others have

demonstrated that IPH on MR imaging is a strong predictor of future cerebrovascular events.⁴⁻⁶ This finding has led to the recognition of IPH as a key marker and pathologic factor contributing to plaque vulnerability.

However, the underlying mechanisms of IPH development are not completely understood. Most often, leakage of erythrocytes from intraplaque microvessels is proposed as a cause for IPH.^{7,8} In contrast, we recently observed fewer microvessels in plaques with IPH,⁹ suggesting that damage to the plaque luminal surface such as fissures and rupture of the fibrous cap (FC) could contribute to IPH.^{8,10} It was demonstrated in histologic specimens that IPH occurs more frequently in the proximal part of the plaque,^{11,12} where the biomechanical wall stress is usually higher,^{13–16} due to arterial pressure wave reflection. In a histopathologic study, we demonstrated that IPH occurred in regions with FC fissures and juxtaluminal calcifications. Juxtaluminal calcifications may lead to increased biomechanical wall stress.¹⁷ Fissures were found in 58% of plaques with grossly intact luminal surfaces. Most of the fissures (88%) occurred in the proximal region of the plaque. The fissures were connected to IPH (92%) and calcifications (43%), while they were connected to microvessels in only 25% of cases.¹⁷

Previous histologic studies were dependent on patient populations that underwent carotid endarterectomy, usually patients with severe carotid stenosis. MR imaging allows investigation of carotid plaques, even in patients with a lower grade of stenosis in which the arterial pressure wave reflection will be less severe.^{18–20}

This study aimed to investigate, noninvasively, whether there is a difference in volume of IPH and the status of the FC in the proximal-versus-distal regions in a relatively large group of patients with stroke with mild-to-moderate carotid stenosis and IPH.

MATERIALS AND METHODS

Study Design

Baseline MR imaging data were analyzed from patients included in the Plaque at Risk (PARISK) study that demonstrated IPH. PARISK is a large, prospective, multicenter cohort study investigating whether plaque imaging enables us to better identify patients with carotid stenosis who have an increased stroke risk.²¹ Patients with a recent (<3 months) TIA or ischemic stroke in the anterior circulation and carotid artery plaque of >2 mm but <70% stenosis ipsilateral to the side of TIA/stroke were prospectively included. The degree of stenosis was determined with Doppler sonography or with CTA. An upper cutoff value of 70% was used on the basis of the NASCET criteria.²² Institutional medical ethical committee approval was obtained, and all patients provided written informed consent.

MRI

The MR imaging protocol has been described in detail previously.²¹

In brief, multisequence carotid MR imaging was performed on a 3T whole-body scanner (Achieva or Ingenia, Philips Healthcare, or Discovery MR 750, GE Healthcare). A dedicated 8-channel phased-array coil (Shanghai Chenguang Medical Technologies) or a 4-channel carotid coil (PACC-ST30, Machnet B.V. Roden, the Netherlands) was used. Dedicated vessel wall image-analysis software (VesselMass; Leiden University Medical Center, the Netherlands) was used to analyze the MR images of the ipsilateral carotid plaque. After an extensive training period and demonstrating good interobserver agreement with a validation set that was previously delineated in consensus by experts (with >7 and >10 years of experience, respectively), the trained observers

FIG 1. Transversal MR images of carotid plaque in the right carotid artery. We acquired the following MR images: precontrast T1-weighted QIR TSE (A), postcontrast T1-weighted QIR TSE (B), T1-weighted inversion recovery turbo field echo (C). D, The same image as in B, including the contours delineating intraplaque hemorrhage and the inner and outer vessel wall: white = lumen, gray = outer vessel wall, black = intraplaque hemorrhage. C, A hyperintense signal in the bulk of the plaque can be clearly observed, indicating the presence of intraplaque hemorrhage (black asterisk). B, An interruption of the signal enhancement adjoining the lumen can be observed, indicating a TRFC (white arrow).

manually delineated the outer vessel wall, luminal area, and plaque components as previously described.²³ Image quality was rated on a 5-point scale.²⁴ Patients were excluded if the mean image quality score was <2.

The vessel wall and luminal area were delineated on the pre-contrast T1-weighted double inversion recovery FSE images (center 2) or the quadruple inversion recovery turbo spin-echo (QIR TSE) (center 1, 3, and 4) images. IPH delineation was performed on T1-weighted inversion recovery turbo field echo images (center 1, 3, and 4) or 3D T1-weighted fat-suppressed spoiled gradient-echo images (center 2).

IPH was delineated by visual observation and was defined as hyperintense signal within the bulk of the plaque compared with the adjacent sternocleidomastoid muscle and was manually delineated per section by the trained observers. FC status was dichotomized as thick versus thin or ruptured.²⁵ When a continuous signal enhancement on the postcontrast images between the lipid rich necrotic core and the lumen was identified, the FC status was classified as “intact and thick.” When no or an interrupted area of enhancement was identified, the FC status was classified as “thin and/or ruptured.” In slices without a lipid rich necrotic core, there is no interrupted area of signal enhancement; therefore, the status of the FC is scored by definition as “intact and thick” (Fig 1).

Previously, we have shown that our method of scoring IPH demonstrated good agreement between MR imaging and histology.²⁶ Interobserver reproducibility for the detection of IPH was very good ($\kappa = 0.86$). We also demonstrated an overall very good interobserver reproducibility of MR image analysis (for carotid

FIG 2. A patient's dataset acquired with an inversion recovery turbo field echo sequence. Delineation of the inner and outer vessel walls and IPH in every 2-mm-thick MR imaging section proximal and distal to the section with the narrowest lumen (0 mm). Gray outline = outer vessel wall, white outline = inner vessel wall, black outline = IPH, white arrow (−6 mm to +2 mm) = MR imaging slices in which the FC status is scored as thin or ruptured. The status of the FC was determined by using the postcontrast T1-weighted QIR TSE sequence. There is a larger volume of IPH at the proximal side of the section with the narrowest lumen (0 mm), and most of the slices with a TRFC are also located at the proximal side.

lumen volume, wall volume, and total vessel volume: intraclass correlation coefficient/coefficient of variation = 0.96/7.7%, 0.95/8.8%, and 0.92/12.8%, respectively).²⁷ Interobserver reproducibility of FC status assessment was good ($\kappa = 0.60$ – 0.71).²⁸ Also, we have previously shown a very good overall interscan/intraobserver reproducibility in a study in which patients were scanned twice within a mean of 4 (SD, 2.9) days (for carotid lumen volume and wall volume: intraclass coefficient/coefficient of variation = 0.99/7.2% and 0.99/7.1%, respectively).²⁷ The interscan/intraobserver reproducibility for the detection of IPH and FC status were very good ($\kappa = 1.00$).²⁷ On the basis of these delineations, the dedicated vessel wall imaging software package automatically calculates the luminal and vessel wall area and the areas of each plaque component per section. Using the vessel wall and IPH areas, we calculated the percentage of IPH of the total vessel wall area per section. Starting at the section with the narrowest lumen, the IPH area and the presence of a thin/ruptured fibrous cap (TRFC) were determined for the neighboring proximal and distal slices at an interval of 2 mm (ie, the MR imaging section thickness) (Fig 2).

Plaque Composition in Proximal-versus-Distal Regions

The proximal region of the plaque is defined as the region proximal to the imaging section with the narrowest lumen (lumen with the absolute lowest area based on luminal contour). The vessel wall area was calculated for each MR imaging section. We generated a histogram of the distribution of the mean IPH area percentage. In addition, we also calculated differences in absolute areas of IPH between the proximal and distal parts of the plaque. The distribution of MR imaging slices with a TRFC at each MR imaging section position proximal and distal to the MR imaging section with the narrowest lumen was also assessed. Section

positions with data from <25 patients are excluded in these histograms because of the small statistical power.

Statistical Analyses

Statistical analyses were performed using SPSS 24.0 (IBM). A P value < .05 was considered statistically significant. To analyze the differences between proximal and distal areas of IPH, we used a paired t test to compare the slices proximal (− n) and distal (+ n) to the section with the narrowest lumen (ie, Section 0). The paired t test was also used to test the overall difference in absolute IPH area between the proximal and distal regions. A McNemar test was used to analyze differences in proportions of the FC status between the proximal and distal slices, per section and overall per patient.

RESULTS

Of 244 included patients, 6 patients withdrew from the study. Of the remaining 238 patients, another 14 patients were excluded due to bad quality scores of the MR imaging ($n = 4$), incomplete MR imaging protocol ($n = 2$), or absence of MR imaging data due to claustrophobia ($n = 6$) or obesity ($n = 2$). Of the remaining 224 patients, 88 patients (39%) demonstrated IPH on the ipsilateral side. Baseline patient characteristics are shown in the Online Supplemental Data. For the analysis of the FC status, another 5 patients were excluded because no post-contrast MR imaging was available (Online Supplemental Data).

The mean IPH area percentage was significantly larger in the proximal part of the plaque (Fig 3A). The largest mean IPH area percentage is observed 4 mm proximal to the narrowest lumen. The proximal-versus-distal area percentages of IPH are at 2, 4, and 6 mm from the narrowest lumen, respectively: 14.4% versus 9.6% ($P = .04$), 14.7% versus 5.4% ($P < .001$), and 11.1% versus 2.2% ($P = .001$). The MR images at 8 and 10 mm from the narrowest lumen also show a higher mean area percentage of IPH proximal compared with distal; however, this difference was not significant (7.5% versus 2.2%, $P = .056$; 5% versus 1.1%, $P = .077$) (Table 1). Also, the absolute IPH area in the proximal region was significantly higher compared with the distal region at 2, 4, 6, 8, and 10 mm from the narrowest lumen, respectively (0.11 versus 0.07 cm², $P = .019$; 0.12 versus 0.04 cm², $P < .001$; 0.10 versus 0.01 cm², $P < .001$; 0.06 versus 0.01 cm², $P = .005$; and 0.03 versus 0.0003 cm², $P = .004$).

In these patients with IPH, 76% demonstrated a TRFC. The proximal region of the plaque in patients with IPH showed a higher prevalence of a TRFC compared with the distal region at 2, 4, 6, and 8 mm from the MR imaging section with the narrowest lumen, respectively: 33.7% versus 18.1%, $P = .007$; 36.1% versus 7.2%, $P < .001$; 33.7% versus 2.4%, $P = .001$; and 30.1% versus 3.6%, $P = .022$. At 10 mm from the narrowest lumen, the

FIG 3. A, Histogram showing significantly larger mean IPH areas in the proximal region of the plaque compared with the distal region. Mean IPH area percentages are shown for each section in relation to the smallest lumen. The *white bar* indicates the section with the narrowest lumen (distance = 0 mm), the bars on the left with the negative numbers are slices proximal (proximally), and the bars on the right with the positive numbers indicate the slices distal to the smallest lumen. Each section has a thickness of 2 mm. An *asterisk* indicates a statistically significant difference ($P < .05$) between the proximal and distal slices using a paired t test. B, Prevalence of a TRFC plotted for each section position with respect to the section with the smallest lumen (0). The bars on the left with the negative numbers are slices proximal, and the bars on the right with the positive numbers indicate the slices distal to the smallest lumen. An *asterisk* indicates a statistically significant difference ($P < .05$) between the proximal and distal slices using a McNemar test.

Table 1: Differences in mean IPH area (% of total vessel wall) between proximal and distal regions

Longitudinal Distance from Section with Smallest Lumen (mm)	No. of Slices Where Proximal and Distal Sections Are Available	Mean % IPH with Respect to Total Vessel Wall Area in the Proximal Region	Mean % IPH with Respect to Total Vessel Wall Area in the Distal Region	P Value
2	66	14.4 (SD, 1.9)	9.6 (SD, 2.1)	.040
4	59	14.7 (SD, 1.7)	5.4 (SD, 1.8)	<.001
6	45	11.1 (SD, 1.6)	2.2 (SD, 1.3)	.001
8	39	7.5 (SD, 1.5)	2.2 (SD, 1.5)	.056
10	34	5.0 (SD, 1.4)	1.1 (SD, 1)	.077

Table 2: Differences in prevalence of a TRFC between proximal and distal regions

Longitudinal Distance from Section with Narrowest Lumen (mm)	No. of Slices Where Proximal and Distal Sections Are Available	TRFC (No.) (%) Proximal Region	TRFC (No.) (%) Distal Region	P Value
2	63	28 (33.7)	15 (18.1)	.007
4	56	30 (36.1)	6 (7.2)	<.001
6	43	28 (33.7)	2 (2.4)	.001
8	38	25 (30.1)	3 (3.6)	.022
10	33	16 (19.3)	0 (0)	1.0

prevalence of a TRFC was also higher in the proximal region; however, it was not significant (19.3% versus 0%; $P = 1.0$) (Table 2). Overall, 66 (75%) patients demonstrated a TRFC on the proximal side, while this number was 19 (22%) on the distal side ($P < .001$) (Fig 3B).

To investigate whether the position of the stenosis relative to the carotid bifurcation affects the distribution of intraplaque hemorrhage, we divided the patients into 2 groups, ie, 50% of the patients with the most distal position of the stenosis and 50% of the patients with the most proximal position. The median difference in the position of the narrowest lumen with respect to the bifurcation was 10 mm

between these 2 groups. Both groups showed more IPH at the proximal side of the carotid plaque (data not shown).

DISCUSSION

The present study demonstrates larger mean IPH areas on the proximal region compared with the distal region of carotid plaques assessed with MR imaging in patients with TIA and stroke with mild-to-moderate carotid artery stenosis. Additionally, we found that TRFCs are more frequently located in the proximal region.

The higher prevalence of a TRFC on the proximal side of the plaques was also reported in a previous study with symptomatic and asymptomatic individuals.²⁹ This could be caused by differences in

the wall stress and wall shear stress between the upstream and downstream parts of the plaque. Similarly, increased prevalence of ulcerations in the proximal region of the carotid atherosclerotic plaque has been reported.^{30,31} The increased prevalence of a TRFC on the proximal side could be related to the increased amount of intraplaque hemorrhage in this region because IPH might also develop from the luminal side via fissures or rupture of the FC.¹⁷ A previous PARISK substudy has shown an association between the disrupted plaque surface and intraplaque hemorrhage on MR imaging.¹⁰

Previously, Fagerberg et al¹¹ also described a higher incidence of severe carotid atherosclerotic lesions (containing IPH, macrophages, TRFC) proximal compared with distal in histopathologic specimens. Their population consisted of 40 patients scheduled for carotid endarterectomy with severe stenosis, while patients included in our analysis had a mild-to-moderate stenosis. Yilmaz et al²⁹ and Dirksen et al³² also demonstrated significantly more macrophages and rupture sites at the proximal side in patients with carotid stenosis who underwent carotid endarterectomy. Yilmaz et al found an equal prevalence of intraplaque hemorrhage between the proximal and distal regions (22% versus 23%) in their study of symptomatic and asymptomatic patients with carotid endarterectomy with >70% carotid stenosis.²⁹ However, they did not investigate differences in the area of IPH. Our results also demonstrate that in a group of patients with a mild-to-moderate degree of stenosis in which the arterial pressure wave reflection is less severe, the proximal region still shows significantly more IPH. Thus, also in this population, biomechanical or hemodynamic factors may relate to IPH.

The larger areas of IPH on the proximal part of the plaque may be related to differences in wall stress, which is often increased in the proximal part of the plaque¹³⁻¹⁶ due to arterial pressure wave reflection at the stenosis. The local blood pressure is typically 3 orders of magnitude larger than wall shear stress³³ and, therefore, is the dominant factor for plaque deformation and plaque rupture.³⁴ A large population study, eg, the Rotterdam Study, demonstrated that pulse pressure, the driving force for plaque deformation, is the strongest determinant of IPH, independent of cardiovascular disease risk factors and other blood pressure components.³⁵ Plaque deformation could lead to local tissue damage such as fissures in the FC or rupture of microvessels, causing development or progression of IPH. Most interesting, population studies also showed that pulse pressure is an independent predictor of coronary heart disease,³⁵ cardiovascular mortality in men,³⁶ multiple adverse cardiovascular outcomes,³⁷ and stroke.³⁸ The latter meta-analysis demonstrated that a relatively small increase in pulse pressure (10 mm Hg) was associated with the occurrence of stroke.³⁸ Therefore, studies have recently been advocated to assess therapies targeted at a reduction of pulse pressure.³⁸

Previous studies have assessed plaque biomechanics using computational models with inherent assumptions. Most of these studies focused on plaque rupture rather than IPH development.^{39,40} Huang et al⁴¹ showed that by using an image-based computational model in 5 patients, the IPH is associated with higher structural wall stress. Teng et al⁴² demonstrated that by using a numeric model based on 4 surgery specimens, local tissue deformations were larger around microvasculature surrounded by red blood cells, indicative of IPH.

Wall stress is not to be confused with wall shear stress, caused by frictional (eg, hemodynamic) forces due to blood flow. Wall shear stress is usually also higher in the upstream region with laminar flow, while the turbulent flow downstream of the maximal stenosis is associated with low shear stress levels.^{11,12,14,33,43-47} High wall shear stress promotes apoptosis of vascular smooth-muscle cells.⁴⁸ It also leads to an increased expression of endothelial adhesion molecules, resulting in an accumulation of macrophages,³² which will result in an increased amount of metalloproteinases, which can break down the matrix of the overlying FC and, therefore, contribute to destabilization of the plaque.^{12,30,32} This will tip the scale toward matrix breakdown instead of cap-reinforcing matrix synthesis by smooth-muscle cells.¹⁴ Thus, increased wall shear stress in the upstream region may lead to degradation of the FC, which can also contribute to the development of IPH.

A limitation of the present study is the lack of hemodynamic and biomechanical data (ie, the distribution of wall stress and wall shear stress). Computational fluid dynamics and 4D flow MR imaging can be used to determine wall stress and wall shear stress.^{46,47} Future studies are warranted that include computational fluid dynamics or 4D flow MR imaging to directly relate the local distribution of IPH and TRFC to wall stress and wall shear stress. If a causal relation is proved, it may lead to evaluation of new treatment options, such as pulse-pressure reduction.

Another limitation in the PARISK study is that different scanners and coils were used at different centers. Consequently, there were differences in the image quality of datasets coming from different centers.

CONCLUSIONS

We demonstrated that IPH is more prevalent on the proximal side of the plaque compared with the distal side in patients with mild-to-moderate stenosis. This prevalence may indicate that biomechanical and hemodynamic factors play an important role in the development of IPH. The results of our study suggest that radiologists could pay attention to whether they observe abnormal soft tissue in the proximal region of the plaque when reviewing carotid MRA and CTA examinations.
