ABSTRACT

SUMMARY: The neuropathogenetic processes underlying essential tremor appear to cause subtle morphologic changes in neural networks that include multiple brain structures, primarily the cerebellum, brain stem, frontal lobes, and thalamus. One of the main challenges of neuroimaging in essential tremor is differentiating disease-specific markers from the spectrum of structural changes that occur due to aging. This review discusses recent neuroimaging studies in the light of current knowledge of the neuropsychology and pathology of the disease. We suggest that the application of multiple macroscopic and microscopic neuroimaging modalities, combined with personalized information relative to cognitive and behavioral symptoms, is the prerequisite for a comprehensive classification and correct diagnosis of essential tremor.

ABBREVIATIONS: ET = essential tremor

Essential tremor (ET) is one of the most common yet least understood movement disorders. It is primarily characterized by a shaking of the hands and forearms that is evident during simple voluntary actions, such as drinking, pouring, eating, or writing. For this reason, in addition to causing obvious disruption of daily activities, patients with ET often avoid social situations, even though they develop strategies to cope with the condition. Tremor is not limited to the upper limbs; the head, neck, voice, legs, or trunk may also be affected. Although ET is much more common in the elderly, the tremors can appear in children and young adults. Therefore, it cannot be considered purely an age-related disease, nor is it clearly sex-specific.

Despite the serious impairment that most patients experience, ET was, until recently, viewed merely as a benign, monosymptomatic (ie, motor) condition. Increased public awareness and new research have shifted the perception of ET to that of an actual neurodegenerative disease that is characterized by motor symptoms and cognitive changes. Nevertheless, unlike other neurologic conditions such as Alzheimer and Parkinson diseases, for which the dynamics and the topography of degeneration are reasonably well-mapped, the neuropathologic phenomena underlying ET seem to be much more subtle and their distribution, more elusive.

The Diagnosis of ET Is Not Definitive

Given that definitive radiologic and pathologic criteria do not exist, the diagnosis of ET is based solely on behavioral symptoms. Relevant factors to establish a diagnosis and distinguish ET from other movement disorders include the age of onset, the evolution of clinical signs with time, which factors aggravate the symptoms, past or chronic exposure to toxic substances (heavy metals in particular), and family history.

In the case of other neurodegenerative disorders, the diagnosis of the disease can be validated at postmortem examination. For example, postmortem gross dissection of the brain of patients with Parkinson disease reveals lack of pigmentation in the substantia nigra. Cortical thinning and enlargement of the ventricles are macroscopic indicators of Alzheimer disease pathology, which is ultimately confirmed when plaques and tangles are present in silver-stained histologic preparations. The distribution of Alzheimer disease and Parkinson disease pathology follows a very con-
were thoroughly characterized. A study of collections of brain specimens donated by patients who postmortem. Hence, it is important to invest in the curation and cell types may emerge as more brain specimens are examined ever, that ET-specific patterns of the distribution of susceptible symptoms. The affected functions are fairly heterogeneous, in-diagnostic criteria currently used does not include cognitive an increasing body of neuropsychological studies of ET, the set of distribution of cellular-level pathology. It is conceivable, how-
neuropathologic examination may not be adequate to map the distribution of cellular-level pathology. It is conceivable, how-
however, that ET-specific patterns of the distribution of susceptible cell types may emerge as more brain specimens are examined postmortem. Hence, it is important to invest in the curation and study of collections of brain specimens donated by patients who were thoroughly characterized.

Cognitive Deficits in ET
As mentioned above, ET is not a purely motor disorder but has instead been linked to additional mild cognitive deficits. Despite an increasing body of neuropsychological studies of ET, the set of diagnostic criteria currently used does not include cognitive symptoms. The affected functions are fairly heterogeneous, including impairments in attention, executive function, verbal flu-
ecy, visuospatial functioning, memory, and working memory. A clear neuropsychological profile of ET is needed, and the patho-
physiology of these behavioral symptoms remains to be established.

When patients with ET were asked to perform a task measur-
ing selective attention and response inhibition as well as a verbal working memory task known to involve cerebellar circuits, their performance was comparable with that of controls. However, neural overactivation was detected, likely reflecting compensatory responses to subtle cognitive deficits. The question of whether this compensation fails as the disease progresses, which would imply a degenerative component, needs to be explored with longitudinal studies.

In the context of neuropsychological symptoms, cerebellar disease and damage have been associated with a pattern of cognitive deficits similar to that observed in ET. The deficits seen in individuals with cerebellar lesions are believed to be produced by a disruption in the communication processes between the cerebellum and the prefrontal cortex via parietal, temporal, and limbic structures.

Diverse Etiologic Factors in ET
As mentioned above, tremor onset and progression are important for diagnosing ET; however, its etiology has not been ascertained. The “usual suspects” in terms of risk factors are aging, specific environmental agents, and hereditary predisposition. Discrepancies between multisite genetic studies and the expression of diverse phenotypes in the same family suggest genetic heterogeneity. The logistics and the data to support large-scale neuroimaging studies combined with genetic studies to identify variants associated with putative noninvasive markers of ET are currently lacking. Therefore, the focus should be placed on developing accurate methodologies to identify neuroimaging markers and relate these to individual histories and etiologies.

Environmental factors discussed in the context of ET include increased blood levels of lead and beta-carboline alkaloids. These neurotoxins cause damage to the cerebellum and the olivary-cerebellar tract. Toxicologic research to evaluate accumulation of agents in the tissue from multiple brain structures could reveal buildup patterns in the brain of patients with ET. Whole-brain, noninvasive imaging techniques could also be used to relate neurodegeneration in the brain to other measures of toxin accumulation, such as lead poisoning.

Options and Reticence in Treatment
The symptoms of ET are treated pharmacologically only when the tremor is severe enough to interfere significantly with the performance of daily activities. The 2 most commonly prescribed drugs are primidone, an anticonvulsant, and propranolol, a beta-adrener-
gic-blocking agent. Medication may be taken either on a daily basis or as needed, for instance, before a social event. Crucially, treatment is ineffective in >30% of the patient population. These statistics are partly responsible for many patients not seeking or adhering to treatment unless the tremor is intolerable.

In the most severe and pharmacologically unresponsive cases, deep brain stimulation of the thalamus can be effective in subduing and even eliminating tremor. ET symptoms are reduced when the electrode is positioned within the ventral intermediate nucleus of the thalamus, a region that receives input from the striatum (specifically, the globus pallidus) and the cerebellum and, in turn, projects to the motor cortex. The fact that deep
brain stimulation works suggests not only that multiple con-
ected brain regions are involved in the production of the tremors
but also that ET shares common neurologic substrates with Par-
kinson disease, for which deep brain stimulation is an established
palliative procedure.

Not surprisingly, alcohol relieves tremor symptoms in many
patients with ET,20 likely via the inhibition of glutamatergic path-
ways, but only temporarily. As the effects of ethanol wear off, the
tremor symptoms actually worsen. Most interesting, transcranial
magnetic stimulation, applied on the occipital area (in the region
of the inion), has the same temporary mitigating effect as ethanol
on tremor symptoms.21 Given the shallow range of the magnetic
pulses in transcranial magnetic stimulation, unless the visual cor-
tex is inexplicably implicated in the disease, we conclude that the
cerebellum is at least partially involved in tremor and that the
body of research that focused on this structure is vindicated.

**ET and the Aging Brain**

It is difficult (if not impractical) to distinguish ET-related pathol-
ogy from more general age-related structural changes that are
detectable with MR imaging. ET is more prevalent among the
elderly,1 and neuroimaging must inevitably contend with this po-
tential bias. If the onset of ET occurs later in life (ie, after 65 years
of age), the progression of tremor symptoms is faster and more
severe degenerative pathology in the cerebellum occurs.22 This is
puzzling because one would expect a greater accumulation of de-
generation at the cellular level in longer-standing early-onset
cases.

From a cognitive perspective, ET has also been linked to a
faster decline compared with healthy age-matched subjects.23
Furthermore, late-onset ET has been linked to an increased risk of
dementia.11 The relationship between cognitive decline and
tremor symptoms is unclear. However, including well-defined
cohorts with ET in the context of large-scale longitudinal neuro-
imaging studies that also track cognitive functioning could iden-
tify anomalous rates of cognitive decline and patterns of cerebral
atrophy as valuable predictive indicators of ET. To be revealed,
these effects may require specialized imaging and analysis meth-
ods. As a start, given that many individuals with ET do not tend to
volunteer information about their condition unless a diagnosis is
made and the personnel who perform the scans are not trained (or
instructed) to pay attention to the signs of ET, it would be useful
to screen for ET in participants of abundant ongoing imaging
studies.24

**The Lack of a Definitive Neuropathologic Signature for ET**

At least 2 separate histopathologic features have been observed
postmortem in samples of brains of patients with ET: loss of Pur-
kine cells in the cerebellum (in two-thirds of cases examined) and
the presence of Lewy bodies in the brain stem (these features have
never been found in the same brain).25,26 One explanation for this
scenario is that distinct abnormalities at the cellular level are
markers of different subtypes of ET.27

Purkinje cells, which are motor in function, are inhibitory
neurons; therefore, their loss could be linked to hyperactivity of
the cerebellum and, consequently, to tremor symptoms.26 Lewy
bodies concentrate in the locus coeruleus,25 which is the most
important source for norepinephrine in the brain and has major
efferent connections to Purkinje cells in the cerebellum.15 It has,
therefore, been proposed that pathologic changes in the locus
coeruleus may eventually lead to changes in Purkinje cells26 (but
then we should find both features in the same brain). Lewy bodies
are prevalent in tissue from many elderly donors, including those
without neurodegeneration or dementia in the last years of their
lives; thus, it is unlikely that this pathology could ever become the
hallmark for ET.28

“Torpedoes” are attenuated axonal swellings that are believed
to be secondary markers related to the degeneration and death of
Purkinje cells.27 “Torpedo” sounds certainly more rare and ex-
otic, but a review of the literature published on these peculiar
silver-stained structures gives the disappointing result that they
are indeed not characteristic of normal brain aging and they are
not unique to brains of patients with ET either. Finally, 2 histo-
logic studies reported abnormal attenuation of tangled basket
cells surrounding the Purkinje cell bodies29 and increased Berg-
man astrogliosis.27 The cause and effects of these secondary
pathologic changes remain unclear.

The findings reported in this section originate largely from
studies that re-examined the same collection of brain specimens28
(studies on the neuropathology of ET are still conducted by a
handful of laboratories and on very few brains). Any apparent
convergence of results could, therefore, be attributable, at least in
case, to the paucity and redundancy of analyses. However, even
within this small and contained research community, not every-
one agrees with the idea that ET should be seen primarily as a
cerebellar disease.30,31 As mentioned earlier, there may very well
be several subtypes of ET that display different (partly overlap-
ning) pathology. It is possible that the samples studied so far only
show a limited cross-section and incomplete picture of the dis-
ease. In either case, the logical solution is to increase collection
and distribution of research samples for controlled (and repro-
ducible) postmortem studies. Availability of biosamples for stud-
ies of the neuropathology of ET should improve both in terms of
quantity but also in quality—that is, each sample should come
fortified with clinical, neuropsychological, and even radiologic
characterizations.7

**The Need for Neuroimaging Markers as a Diagnostic Tool for ET**

Histologic studies can give a definitive view of the tissue-level
phenomena underlying observed signs of neurologic disease, but
unfortunately, they cannot assist directly with the premorbid de-
tection of pathologic changes. MR imaging, on the contrary, has
promise in terms of predicting and tracking clinical outcomes.
Several MR imaging studies, published in the past decade, sought
to detect ET-specific morphologic abnormalities. Most studies
highlighted atrophic changes in different lobules of the cerebel-
rum32,33 (but also in other brain regions34,35).

Patients with both head and hand tremor showed reduced GM
volume in the vermis of the cerebellum, compared with patients
with only hand tremor.32 Increased GM and WM atrophy (rela-
tive to analogous measures in control subjects) was also detected
in the frontal, occipital, parietal, and temporal lobes and the me-
dulla and insula.34,35 Taken at face value, these reports suggest a
generalized effect of ET on the cerebellothalamocortical network, but these positive results are not ubiquitous in the literature. The lack of definitive macroscopic markers for cerebellar atrophy and ET-specific morphologic changes reflect the ambiguous picture that currently describes pathology at the microscopic level.

Some questions regarding ET pathology could be explored with existing tools. For example, it should be possible to determine whether ET affects the entire cerebellum or whether it selectively affects specific lobules or nuclei of the cerebellum. This distinction may be of particular interest because the anterior lobe of the cerebellum is associated with motor function while the posterior regions are involved in cognition. In particular, neural activation patterns among the frontal regions and the cerebellar hemispheres and the dentate nucleus are involved in executive functioning and verbal working memory. Perhaps ET affects the anterior regions of the cerebellum first, leading to motor symptoms, and then spreads to the posterior regions as the disease progresses, leading to cognitive impairments.

Do patients with ET with more severe cognitive impairments also show more severe atrophy in the posterior lobules of the cerebellum? Remarkably, none of the structural MR imaging studies discussed in this review evaluated the level of cognitive impairment in their study participants. In addition to mapping the topography of structural abnormalities, defining the relative changes in different tissue compartments by using specialized imaging sequences and morphometric analyses could lead to identifying specific degeneration patterns in ET, distinguishable from those occurring due to aging.

Preliminary findings from a small ET pilot study have revealed selective atrophy in the cerebellar cortex in the absence of overall cortical atrophy. In particular, the sulci of the cerebellum were found to be deeper and wider, likely indicating selective deterioration of cerebellar GM. Most interesting, the patients showed no overall volume loss in the cerebellum and minimal cerebral cortical atrophy. In addition to neuroimaging, subjects also underwent detailed neuropsychological assessment and tremor quantification, which revealed different cognitive profiles and tremor characteristics. These preliminary findings suggest that cerebellar cortical atrophy may serve as a potential selective neuroimaging marker for ET, separate from the other effects of age-related degeneration.

**Evaluating Neural Networks Rather than Localized Brain Regions**

Undoubtedly, evidence from most published neuroimaging studies suggests that the cerebellum or neural networks involving the cerebellum play a key role in the pathophysiology of ET. The unresolved question is whether the tremors originate in the cerebellum and are subsequently mediated by other structures within that network or whether a concerted disruption in connectivity between several brain structures causes ET-related symptoms.

MR-based diffusion imaging measures water diffusion and diffusion directionality along axons as an indicator of axonal injury. In ET research, diffusion imaging studies focus on fiber tracts projecting to and from the cerebellum. The first study to explore functional connectivity in patients with ET compared with healthy controls used DWI. No major structural abnormalities were detected in the pons, middle cerebellar peduncles, cerebellar WM, dentate nucleus, red nucleus, thalamus, caudate, putamen, pallidum, and frontal WM. Yet, DWI may not be sufficiently sensitive because it measures diffusion in only 1 direction as opposed to DTI, which measures diffusion in multiple directions. If that were the case in this study, more subtle WM abnormalities may have been overlooked in the ET cohort.

Subsequent DTI studies explored WM fiber integrity and directionality in patients with ET. DTI measures mean diffusivity and ADC, as markers of the magnitude of water diffusion along fiber tracts, and fractional anisotropy, as a marker of the directionality of water diffusion. Decreased fractional anisotropy and increased mean diffusivity/ADC indicate WM damage. Increased ADC values of the red nucleus, indicative of neuronal loss or injury in this region, have been reported in patients with ET compared with healthy controls.

Because it is possible that pathologic changes in ET may spread with time, affecting various brain regions, the red nucleus may be a structure affected earlier than others. However, this explanation is unlikely because abnormal DTI values in the red nucleus are not a consistent finding in patients with ET. Likewise, while longer disease duration did correlate with lower fractional anisotropy values in the dentate nucleus in 1 study, a relationship between disease duration or tremor severity and DTI measures was not confirmed by others. This discrepancy shows that the question of whether ET is progressive warrants further study.

That the tremor origin has not been localized in ET thus far suggests that an abnormal communication between several brain regions causes motor symptoms. Several neural loops have been proposed to be affected. For instance, DTI values of the superior cerebellar peduncle fiber tracts, which receive input from the dentate nucleus and send output to the red nucleus, indicated damaged WM in a study by Nicoletti et al. Based on these findings, a disturbance in the dentatorubro-olivary tract (ie, neural fibers connecting the dentate nucleus via the superior cerebellar peduncles with the red nucleus and inferior olive) may underlie tremor genesis in ET.

A later study, however, failed to find WM abnormalities in the middle and superior cerebellar peduncles. Instead, compromised fiber integrity was found in the inferior cerebellar peduncles, suggesting a disturbance in tracts projecting through the cerebellum via the inferior cerebellar peduncles. Based on reduced fractional anisotropy in the pons, cerebellum, and midbrain and extensive WM damage in the frontal cortex and temporoparietal regions in patients with ET, others proposed that an abnormality in the cerebellothalamocorticocerebellar loop is responsible for the tremor. Similarly, compromised WM has been reported in frontoparietal regions, cerebral hemispheres, the thalamus, and brainstem.

In summary, with the exception of 1 study, most DTI research in ET demonstrated that widespread disintegration of cerebral and cerebellar fiber tracts is common and likely underlies tremor generation. Although it is known that DTI measures are indicators for WM integrity, the exact nature underlying these pathologic processes is unknown. Whether demyelination,
myelin injury, neuronal loss, or other processes underlie abnormal DTI values in patients with ET remains to be ascertained.

**Potential Bias in ET Neuroimaging Studies**

The obvious discrepancy between the results of different studies may be due to a number of methodologic inconsistencies. For example, while some studies used region-of-interest–based analysis methods, others used whole-brain analysis approaches or both. Region-of-interest–based analysis is more biased, and overall structural abnormalities may be overlooked. Whole-brain analysis, on the other hand, allows exploration of widespread networks but may not be specific enough, with the risk of ignoring smaller regions and nuclei.

The data that make up all of the neuroimaging descriptions of ET were acquired at different magnet field strengths (most at 1.5T and 3T). Accordingly, contrast and resolution, the parameters that, for the most part, guide the interpretation and analysis of the images, cannot be assumed constant. The cerebellum is a very complex structure in terms of geometry, and the scale of morphologic features (and their aberrations) is much smaller than that in the cerebral hemispheres. The fractal gyration of the cerebellar cortex is an exquisite example of this principle. Cerebellar anatomy is extremely difficult to visualize at the relatively low resolutions afforded by clinical scans (Fig 1). The need for validation studies across scanners of different manufacturers and with different field strengths is even more crucial for ET than for other areas of investigation using MR imaging to model cerebral structures.

Other factors that varied considerably among studies are subjective and tremor characteristics. Because it is likely that ET is a heterogeneous disease with different phenotypes, the general ET diagnosis could be inadequate to define cohorts undergoing imaging studies. It may be necessary to screen for more subtle differences between patients, such as the pattern of tremor manifestation (circadian fluctuations, effect of medication, and so forth), the history and severity of the disease (these could be documented via personalized medical history and could be measured quantitatively with commercially available tremmeters, respectively), and simple genetics (discriminating between familial-versus-nonfamilial ET).

While some patient cohorts were limited to subjects with a family history of ET, others included patients with and without familial ET or did not control for this variable. While a positive family history is not the only factor proposed to play a role in the etiology of ET, this factor should be controlled for, because it could be a possible confounder. That ET often goes undiagnosed for many decades and subjects may not know about the medical history of estranged or deceased relatives should also be taken into consideration.

Finally, only 3 of the neuroimaging studies reviewed included young adults. The age bias toward elderly subjects, not only dictated by the prevalence of the disease among older men and women but also by the predominance of subjects who are retired and amenable to participate and adhere to the research, could overlook crucial clues deposited by ET in otherwise young and “clean” brains. Last, neuroimaging studies might be looking too selectively at structures that are known to be “motor,” such as the cerebellum; the effect is made obvious in Fig 2.

**The Dysfunctional Correlates of ET**

Using PET, researchers have looked for metabolic abnormalities that may trigger the tremor, such as increased blood flow in the cerebellum of patients with ET (compared with control subjects). Patients with ET who underwent PET showed increased blood flow in the striatum, thalamus, and sensorimotor cortex and in the region of the red nucleus. These pontine structures were also implicated by measures of blood flow with fMRI. Bilateral activation of the red nucleus, along with the dentate nuclei and both cerebellar hemispheres, was observed in patients with ET, while control subjects only showed unilateral activation of these regions when they affected tremor with the opposite limb.

PET research has also provided a neurologic explanation for the above-stated fact that consumption of ethanol modulates ET. This effect was mirrored by decreased metabolic rates in the cerebellum and increased activation in the inferior olivary nuclei. Magnetoencephalography, which is characterized by a high temporal resolution, demonstrated coherent activation patterns between the arm muscle and motor cortices, thalamus, brain stem, and cerebellum, suggesting that this network of structures plays a role in ET-related tremor. However, such coherent activation patterns were not confirmed by others questioning the temporal dynamics of the disease.

By measuring the level of various cellular metabolites, in particular NAA and total creatine, MR spectroscopy can localize neuronal injury or loss in the brain. Patients with ET showed reduced NAA/total creatine in the cerebellum, and these values correlated with both age and tremor severity, suggesting the degenerative nature of this disease. The readers of this review will be used to cautionary tales by now; therefore, they will understand that other studies could not confirm the above-stated relationship between metabolic abnormality, age, and tremor.

Due to the poor spatial resolution afforded by MR spectroscopy in most typical clinical and research settings, it was possible to neither measure metabolic levels selectively in smaller nuclei nor distinguish between WM and GM within the cerebellum. In addition, longitudinal measurements in the same subject would also be required to link metabolic changes to the progression of tremor symptoms.

**CONCLUSIONS**

Neuroimaging research in the field of ET has demonstrated that widespread structural changes in cortical and subcortical brain regions and metabolic abnormalities are common in symptomatic patients. Clearly, detecting structural and functional changes in the cerebellum is essential in understanding the neurologic basis of motor and behavioral manifestations of ET. Nevertheless, the detailed characterization of cerebellar abnormalities that can be obtained by applying multiple, noninvasive, and postmortem neuroimaging modalities (at macroscopic and microscopic resolution, respectively) needs to be integrated with a temporal and spatial network-based approach to trace the origin and progression of the symptoms.
Tangible inconsistencies between different ET neuroimaging studies emerge from the review of existing literature. These need to be addressed to resolve potential neuroimaging markers for this condition. Discrepancies could be due to methodologic differences; but different subjects examined may embody different subtypes of ET. The establishment of neuroimaging consortia in the context of which sequences and hardware could be evaluated and calibrated, as well as effective data-sharing mechanisms, could effectively eliminate site-dependent technical idiosyncrasies. Achieving shared neuroimaging resources based on well-defined (and transparent) protocols has proved very successful, and it would be especially effective in the case of ET, for which the neuropathogenesis is so elusive.

The confederation of existing and emerging brain banks that share an interest in ET would create the basis for large-scale histologic studies, thereby gradually assembling the complete cellular-level landscape of the disease from thousands of cases as has been done for Alzheimer and Parkinson diseases. This approach would require not only new investments in resources (brain banks are expensive both in terms of operation and real estate) but also active engagement of the public via “citizen science” and partnerships with advocacy groups, the latter often being tremendously successful in educating and mobilizing patient populations (http://www.essentialtremor.org).

Most important, we believe that it is crucial for future research to aim at the correlation of longitudinal neuroimaging data with neuropsychologic testing, quantitative measurements of tremor characteristics (such as frequency and amplitude), and detailed personal medical and biographic information. Our close interactions with (still) few but exceptionally engaged research participants have demonstrated how varied the symptoms can be and the differences in the history of and attitude toward the condition. Quantitative and qualitative differences among patients with ET are often reflected in the results of the complete spectrum of their tests; further studies will determine whether these personal differences are also traceable to distinct patterns in their individual MR imaging.

ACKNOWLEDGMENTS
The authors would to thank Colleen Sheh for creating the images contained in this manuscript and Clinton and Margaret Spangler for their extraordinary commitment to ET research.
