Radiation Dose for 345 CT-Guided Interlaminar Lumbar Epidural Steroid Injections

A.L. Chang, A.H. Schoenfeld, A.L. Brook, and T.S. Miller

ABSTRACT

BACKGROUND AND PURPOSE: CT guidance is increasingly being used to localize the epidural space during epidural steroid injections. A common concern is that CT may be associated with significantly higher radiation doses compared with conventional fluoroscopy. The goal of this retrospective study was to determine the average dose-length product and effective dose delivered while interlaminar epidural steroid injections are performed and allow comparison with other modalities.

MATERIALS AND METHODS: A total of 281 patients who had undergone 345 consecutive CT-guided epidural steroid injections of the lumbar spine were evaluated for radiation exposure. The dose-length product for each scan was derived from the CT dose index volume and scan length. Effective dose was then calculated from the dose-length product and a $k$ coefficient of 0.015. Procedure time was calculated from the PACS time stamp on the scout image to the last CT image of the last image series.

RESULTS: The average dose-length product across all procedures was $89.6 \pm 3.33 \text{ mGy cm}$, which represents an effective dose of $1.34 \pm 0.05 \text{ mSv}$. No complications from the procedure were observed, and average procedure time was 8 minutes.

CONCLUSIONS: The use of a stationary table and an intermittent scanning technique allow for short procedures and doses that are significantly lower than those of conventional diagnostic CT scans. Furthermore, because CT dose index overestimates radiation dose in stationary table procedures, the actual radiation dose may be even lower than stated here.

ABBREVIATIONS: CTDI = CT dose index; CTDI$_{vol}$ = CT dose index volume; DLP = dose-length product; ED = effective dose; ESI = epidural steroid injection
and includes the contribution to the dose from overlap of dose tails.\textsuperscript{3,4} The measurement of CTDI is made with a pencil-shaped ionization chamber with a standard length of 100 mm in an acrylic cylindrical phantom, which gives rise to the definition of

\[ CTDI_{100} = \frac{1}{NT} \int_{-50 \text{ mm}}^{50 \text{ mm}} D(z)dz. \]

Within the cylindrical phantom, the dose is higher at the periphery of a given section compared with the center, and a weighted version of $CTDI_{100}$ is defined as

\[ CTDI_w = \frac{1}{3} CTDI_{100 \text{ \ center}} + \frac{2}{3} CTDI_{100 \text{ \ edge}}, \]

which averages the dose over the field of view. A 16-cm diameter cylinder is used to measure $CTDI_w$ for head examinations, whereas a diameter of 32 cm is used for body examinations.

The most commonly used form of CTDI in dosimetry is $CTDI_{vol}$ which also incorporates the scanner’s pitch into the dose estimate:

\[ CTDI_{vol} = \frac{1}{\text{pitch}} CTDI_w, \]

where

\[ \text{pitch} = \frac{1}{NT} \]

and $I$ represents the table increment in millimeters (mm) per axial scan. $CTDI_{vol}$ is easily calculated and is available in most scanner output dose tables. The SI unit of measurement of the dose is the milligray (mGy).

Because scans of greater physical length increase with the portion of the body exposed to radiation and thus affect the radiation dose, the DLP was developed to incorporate scan length into the dose calculation: $DLP = CTDI_{vol} \times \text{ scan length (cm)}$. The units of DLP are in milligray centimeters (mGy-cm) and represent the total energy absorbed in the scanned volume.

Lastly, one other common index in dosimetry is ED (measured in millisievert [mSv]), which takes into account that a given radiation dose has different effects on tissues with different sensitivities to radiation. The ED is defined as the summation of the dose to a series of organs multiplied by their weighting factors. However, in CT examinations, the ED can be approximated by the simplified relationship, $ED = \kappa \times DLP$, where $\kappa$ is the conversion coefficient from DLP to ED. The value of the coefficient $\kappa$ depends on the region of the body being scanned. Effective dose is most useful when used as a parameter to compare relative exposure/risk between different types of imaging studies.\textsuperscript{5}

**MATERIALS AND METHODS**

**Study Design**

After receiving approval from the institutional review board, we conducted a retrospective review on 281 consecutive patients undergoing 345 CT-guided interlaminar ESIs in the lumbar spine at a single institution during an 8-month period. All procedures were performed by 1 of 3 interventional neuroradiologists who perform at least 500 CT-guided procedures annually. Patients were seen in an office consultation before the procedure, monitored for 1 hour immediately after the procedure, contacted by phone at 24 hours, and seen in the office 1 month later.

There are several different modes possible with CT; one option is to use CT in a fluoroscopic mode, which provides continuous real-time image collection in a manner similar to traditional fluoroscopy. Another option is to use intermittent scans, where single images are taken serially, either with a foot pedal or remotely at the control station. These scans all occur on a stationary table, so that the same cross section is continually acquired. In our study, images were obtained by use of an intermittent scanning mode. The procedures were conducted at 120 kVp and 50 mA; in a few instances, the milliampere needed to be increased to provide better resolution in patients with a large body habitus.

$CTDI_{vol}$ and DLP displayed in the CT scanner dose report were recorded for each patient. The $CTDI_{vol}$ was also measured under standard conditions with acrylic phantoms and compared with the displayed value to verify its accuracy. The mean deviation of measured versus reported dose was $+1.9\%$ (range, $-6\%$ to $+12\%$ across scanners). The images for each patient were individually reviewed to ensure that each procedure was correctly categorized. We obtained procedure time by comparing the scout image with the last CT image.

**Dose Calculations**

Once the DLP had been collected for each individual case, an ED/DLP conversion coefficient was calculated from the ImPACT CT Patient Dosimetry Calculator version 1.0.2 (ImPACT, London, United Kingdom), a widely available spreadsheet in the ra-
radiation dosimetry community, and by using ICRP 103 weighting factors (Fig 1). By taking into account the affected organs and their specific weighting factors, we estimated the ED/DLP coefficient to be approximately 15 μSv/mGy·cm.7,8

**Technique**

All procedures were performed with intermittent CT guidance by use of LightSpeed RT 16/LightSpeed Xtra scanners (GE Healthcare, Milwaukee, Wisconsin), with 120 kVp, 50 mA, and 0.8-second rotation time. Patients were placed in a prone position. The patient’s back was then marked, prepped, and draped in the usual sterile manner. Several helical images through the target level were then performed to plan trajectory and identify an interruption between the laminae to allow the needle to reach the target epidural space from a posterior (dorsal interlaminar) approach. Lidocaine 2% was used to anesthetize the area, and a 22-gauge spinal needle was then advanced into the epidural space by use of an interlaminar approach. A 3-mL Luer-slip syringe with either 1 mL of air or contrast medium (iohexol 180 mg/mL) was attached to the spinal needle, and a loss-of-resistance technique was used to guide the needle past the ligamentum flavum, and air or iohexol was injected to identify the epidural space. Additional axial images were then obtained to confirm correct placement of the needle. This was repeated until the epidural space was demonstrated with the injection. A steroid/anesthetic mixture of betamethasone sodium phosphate and betamethasone acetate (12–18 mg) and bupivacaine hydrochloride 0.5% (1–3 mL) was injected into the epidural space, and the needle was withdrawn ending the procedure. Any potential complications were recorded and reported according to Society of Interventional Radiology guidelines.9

**RESULTS**

A total of 281 patients underwent 345 CT-guided lumbar ESIs via an interlaminar approach. The average patient age was 59.7 years, 206 (59.7%) were women, and 139 (40.2%) were men. The mean DLP for all procedures was 89.6 ± 3.33 mGy·cm, and the median value was 78.34 mGy·cm. By use of the above-stated ED/DLP conversion factor (also known as the coefficient) of 15 μSv/mGy·cm, we obtained the mean DLP of 281 patients to be 3.35 mSv.10 Intermittent scans also have the advantage of decreasing radiation exposure to the patient and operator,13 with the potential to completely eliminate exposure to the operator when image acquisition is initiated from within the shielded control station.

Our value compares favorably to lumbar radiographs in the lumbar spine, with an estimated 1–1.5 mSv in studies done in the United Kingdom, by the NRCP, and by the UNSCEAR.12,14–16 Schmid et al17 conducted simulations by using Rando phantoms (The Phantom Library, Salem, New York) and estimated that the ED from 4–10 intermittent CT scans ranged from 1.51–3.53 mSv, with 4 scans estimated to be the average number necessary. Thus, our results are near the general predicted range. Schmid et al17 also found that 1–3 minutes of conventional fluoroscopy yielded an ED of 0.41–1.25 mSv, respectively, with 1 minute being the estimated average fluoroscopy time necessary. Kim et al18 also performed a study using phantoms to estimate ESI dose with conventional fluoroscopy and found an estimated ED of 0.93 mSv from a mean clinical procedure time of 40.7 seconds (range, 14.3–95.9 seconds).

Limited work has previously been done on the dose from CT fluoroscopy in ESI; however, Hoang et al19 recently compared CT fluoroscopy with conventional fluoroscopy in lumbar ESIs. They found that conventional fluoroscopy yielded 0.85 mSv from a mean exposure time of 37 seconds, whereas CT fluoroscopy yielded 0.45 mSv with exposure time of 4.7 seconds, though they also performed preliminary planning CTs, which added 2.90 mSv to produce a total dose of 3.35 mSv per procedure.19

A limitation of any study measuring radiation exposure involves the differences between studies in machine types, settings, and even operator skill, which can all affect the exposure time and dose. However, these studies do provide a useful context for understanding and comparing our results with known data on predicted doses for intermittent scans and conventional fluoroscopy.

The traditional drawback to CT use has been its association with increased risk from higher radiation exposures than fluoroscopy.10,11 There are several reasons to quantify radiation exposure in lumbar ESIs. Multiple ESIs are not uncommon for pain relief in some patients, some of whom present at a relatively young age. Repeated radiation exposure over the same anatomic area can increase both deterministic and stochastic radiation-related risks, which makes the determination of exposure from any diagnostic or therapeutic study important.

In our study, the average DLP from use of an interlaminar approach for ESIs was 89.6 ± 3.33 mGy·cm while using an intermittent scanning mode. The conversion of our average DLP to ED by an ED/DLP factor of 15 μSv/mGy·cm yields a value of 1.34 ± 0.05 mSv. By comparison, the average background radiation dose per person in the United States is approximately 3.11 mSv per year, and a regular CT of the abdomen/pelvis is approximately 10 mSv.12 Intermittent scans also have the advantage of decreasing radiation exposure to the patient and operator,13 with the potential to completely eliminate exposure to the operator when image acquisition is initiated from within the shielded control station.

Our value compares favorably to lumbar radiographs in the lumbar spine, with an estimated 1–1.5 mSv in studies done in the United Kingdom, by the NRCP, and by the UNSCEAR.12,14–16 Schmid et al17 conducted simulations by using Rando phantoms (The Phantom Library, Salem, New York) and estimated that the ED from 4–10 intermittent CT scans ranged from 1.51–3.53 mSv, with 4 scans estimated to be the average number necessary. Thus, our results are near the general predicted range. Schmid et al17 also found that 1–3 minutes of conventional fluoroscopy yielded an ED of 0.41–1.25 mSv, respectively, with 1 minute being the estimated average fluoroscopy time necessary. Kim et al18 also performed a study using phantoms to estimate ESI dose with conventional fluoroscopy and found an estimated ED of 0.93 mSv from a mean clinical procedure time of 40.7 seconds (range, 14.3–95.9 seconds).

Limited work has previously been done on the dose from CT fluoroscopy in ESI; however, Hoang et al19 recently compared CT fluoroscopy with conventional fluoroscopy in lumbar ESIs. They found that conventional fluoroscopy yielded 0.85 mSv from a mean exposure time of 37 seconds, whereas CT fluoroscopy yielded 0.45 mSv with exposure time of 4.7 seconds, though they also performed preliminary planning CTs, which added 2.90 mSv to produce a total dose of 3.35 mSv per procedure.19

A limitation of any study measuring radiation exposure involves the differences between studies in machine types, settings, and even operator skill, which can all affect the exposure time and dose. However, these studies do provide a useful context for understanding and comparing our results with known data on predicted doses for intermittent scans and conventional fluoroscopy.

A few values in our data were found to be causing a positive
A factor that can cause an overestimation of ED stems from how CTDI is defined. The definition of CTDI assumes that the table is incrementally advanced through a scan length, which does not apply to interventional procedures utilizing a stationary table. CTDI includes the dose tails resulting from scatter in the integration of the dose, and these dose tails are reduced when a stationary table is used. Several groups have measured the peak skin dose to be only 50%–65% of the stated CTDI_{vol}.\textsuperscript{3,23,24} In fact, Leng et al\textsuperscript{23} used a correction factor of 0.6 × CTDI_{vol} to correct for the dose in interventional intermittent stationary table scans. This finding implies that the intermittent CT dose is potentially even lower than the result reported here. Without very thin thermoluminescent or solid-state dosimeters, it is difficult to know how much lower the actual dose is than when estimated by the CTDI, and doing so would be a next logical step for further research.

The future of CT guidance for procedures in the spine is promising. The ability of CT to provide precise 3D needle localization combined with the radiation exposure results seen here, along with ongoing research currently being conducted on dose reduction methods for CT guidance,\textsuperscript{25} provides great future potential for the use of CT in spinal procedures.

**CONCLUSIONS**

The use of an intermittent scan mode can provide the advantages of CT guidance without necessarily subjecting the patient to excessive radiation; our study found an average ED of 1.34 ± 0.05 mSv per interlaminar ESI in the lumbar spine while using an intermittent scanning mode.
