ABSTRACT

BACKGROUND AND PURPOSE: A substantial portion of clinically diagnosed TIA cases is imaging-negative. The purpose of the current study is to determine if arterial spin-labeling is helpful in detecting perfusion abnormalities in patients presenting clinically with TIA.

MATERIALS AND METHODS: Pseudocontinuous arterial spin-labeling with 3D background-suppressed gradient and spin-echo was acquired on 49 patients suspected of TIA within 24 hours of symptom onset. All patients were free of stroke history and had no lesion-specific findings on general MR, DWI, and MRA sequences. The calculated arterial spin-labeling CBF maps were scored from 1–3 on the basis of presence and severity of perfusion disturbance by 3 independent observers blinded to patient history. An age-matched cohort of 36 patients diagnosed with no cerebrovascular events was evaluated as a control. Interobserver agreement was assessed by use of the Kendall concordance test.

RESULTS: Scoring of perfusion abnormalities on arterial spin-labeling scans of the TIA cohort was highly concordant among the 3 observers (W = 0.812). The sensitivity and specificity of arterial spin-labeling in the diagnosis of perfusion abnormalities in TIA was 55.8% and 90.7%, respectively. In 93.3% (70/75) of the arterial spin-labeling CBF map readings with positive scores (≥2), the brain regions where perfusion abnormalities were identified by 3 observers matched with the neurologic deficits at TIA onset.

CONCLUSIONS: In this preliminary study, arterial spin-labeling showed promise in the detection of perfusion abnormalities that correlated with clinically diagnosed TIA in patients with otherwise normal neuroimaging results.

ABBREVIATIONS: ASL = arterial spin-labeling; ATT = arterial transit time; PCT = contrast-enhanced perfusion CT; PLD = postlabel delay

TIA is traditionally defined as the sudden onset of a neurologic deficit(s) as a result of transient ischemia of the eloquent brain, which resolves completely within 24 hours. TIA is presumed to have a vascular cause and is considered to be an important risk factor for stroke. In practice, the unequivocal diagnosis of TIA has been limited by the high percentage of patients who had suspected neurologic deficits, but lacked confirmatory imaging. This contributes to lack of agreement in the diagnosis of TIA among practicing physicians and has led to proposals advocating the incorporation of imaging data, in addition to clinical findings, in the diagnosis of TIA. For instance, this new paradigm has been adopted by American Stroke Association. In addition to diagnosis, detection of malperfused tissue is considered to be important in understanding the extent of the initial perfusion deficit and may be helpful in guiding therapeutic decisions.

SPECT and contrast-enhanced perfusion CT (PCT) have been previously used to investigate perfusion disturbances in clinical TIA cases. However, these CT-based imaging techniques have several disadvantages including invasiveness, reliance on radioactive materials, adverse reactions to contrast material, as well as technical difficulties in covering large brain volumes. More recently, the introduction of advanced MR imaging technology has enabled better visualization of ischemic cerebral regions corresponding both anatomically and temporally to symptoms of TIA. For example, DWI results were positive for acute ischemic lesions in 24%–40% of patients referred for evaluation of TIA. In addition, contrast-based PWI has shown promise in the identification of abnormalities in approximately one-third of patients with TIA, some of whom had negative DWI results. Nonetheless, a substantial portion of patients diagnosed with TIA clinically lack confirmatory imaging findings.

The arterial spin-labeling (ASL) technique provides CBF measurements without the use of a contrast agent. ASL has shown...
promise in clinical studies of ischemic pathologic conditions, such as acute stroke18-20 and large-artery occlusion.21,22 In a limited number of published studies, ASL has demonstrated a high sensitivity for detection of minor perfusion alterations in patients with TIA.12,23 With the goal of establishing a vascular cause of TIA symptoms, the current study investigated the value of ASL in the detection of hypoperfusion abnormalities in a TIA cohort free of stroke history and without confirmatory findings on standard MR, DWI, and MRA examinations.

MATERIALS AND METHODS

Patients
From an ongoing prospective registry of consecutive patients evaluated for suspected TIA from July 2010 to July 2011 at our medical center, imaging data were selected from all patients who had 1) transient neurologic symptoms judged by clinical neurologists at the end of the evaluation to have a possible vascular cause; 2) no stroke history; 3) MR images performed within 24 hours of symptom onset; and 4) nonspecific findings on general MR, DWI, and MRA examinations. ASL imaging was used only in this retrospective analysis but not in the clinical evaluation of the patients. The selected patients were then followed up in clinic for complaints of any new neurologic symptoms until December 31, 2011, when the study was terminated. A control cohort of age-matched patients (\(n=49\)) and control patients (\(n=36\)) were scored by 3 independent observers (2 board-certified neuroradiologists and 1 nonradiologist physician experienced in MR imaging processing) blinded to patient history. The reading scores, ranging from a scale of 1–3, reflected the presence and severity of the perfusion disturbance (usually hypoperfusion in this study): “1” for normal (no readable altered perfusion), “2” defined as “positive” readings indicating recognizable ischemic lesions (“2” for subtle abnormalities only identified by careful study of ASL CBF maps, and “3” for prominent perfusion deficits easily identified on ASL CBF maps). The laterality of the perfusion disturbance was recorded in patients with hemispheric TIA for comparison with neurologic symptoms at onset. ASL reading scores were compared between patients grouped by field strength (1.5T vs 3T) of the scanner on which ASL images were obtained.

ASL Postprocessing and Evaluation
ASL images were corrected for motion; pair-wise subtracted between labeled and unlabeled images; and averaged to generate mean difference images, or ASL CBF maps. ASL CBF maps of patients with TIA (\(n=49\)) and control patients (\(n=36\)) were scored by 3 independent observers (2 board-certified neuroradiologists and 1 nonradiologist physician experienced in MR imaging processing) blinded to patient history. The reading scores, ranging from a scale of 1–3, reflected the presence and severity of the perfusion disturbance (usually hypoperfusion in this study): “1” for normal (no readable altered perfusion), “2” defined as “positive” readings indicating recognizable ischemic lesions (“2” for subtle abnormalities only identified by careful study of ASL CBF maps, and “3” for prominent perfusion deficits easily identified on ASL CBF maps). The laterality of the perfusion disturbance was recorded in patients with hemispheric TIA for comparison with neurologic symptoms at onset. ASL reading scores were compared between patients grouped by field strength (1.5T vs 3T) of the scanner on which ASL images were obtained.

Statistical Analysis
The agreement in reading scores from 3 observers (\(n=49 \times 3\) for the TIA cohort; \(n=36 \times 3\) for the control cohort) was assessed by use of a Kendall concordance test. Kendall \(W\), also known as the Kendall coefficient of concordance, was calculated to evaluate the degree of consensus. Pooled observations from all 3 observers (\(n=49 \times 3\) for the TIA cohort; \(n=36 \times 3\) for the control cohort) were recorded in a \(2 \times 2\) contingency table reflecting the frequency of true-positive, true-negative, false-positive, and false-
negative observations as rated by ASL CBF maps compared with the clinical diagnosis of TIA (reference standard). A true-positive result was obtained from a patient clinically diagnosed with TIA with an ASL CBF map reading score ≥2. Conversely, a true-negative result was obtained from a control patient with an ASL CBF map reading score of 1. Sensitivity and specificity were calculated. A t test was used to compare ASL reading scores between imaging performed on scanners with different magnetic field strengths (1.5T vs 3T). The significance level was defined as \( P < .05 \) (2-sided).

**RESULTS**

**Patient Characteristics**

From July 2010 to July 2011 at our medical center, we recorded 165 patients who were suspected of having a TIA, among whom 67 (40.6%) had a history of ischemic stroke. In patients who tested negative for a stroke history (98/165), 23 patients (23.4%) had positive DWI findings, and 30 patients (30.6%) had vascular lesions identified by MRA. In this particular subgroup, 4 patients (4.1%) showed positive findings on both DWI and MRA. Finally, 49 patients (50.0%) were “imaging negative” and were selected for our current analysis. Until December 31, 2011, the selected imaging-negative patients with TIA were followed up in clinic for 164–538 days (median, 370 days) for complaints of new neurologic symptoms. Patients did not receive follow-up MR imaging.

Another cohort of 36 age-matched patients (>40 years old), who had received a brain MR imaging scan because of neurologic symptoms thought to be irrelevant to vascular events, was selected from another ongoing prospective registry of consecutive patients during the same period as a control (On-Line Table).

Table 1 shows baseline characteristics of “imaging-negative” patients with TIA (\( n = 49 \)) at symptom onset and control patients.
Evaluation of ASL CBF Maps

Results suggested relatively high concordance scores (Kendall concordance test), indicating good agreement in evaluating ASL CBF maps of both TIA (W = 0.812) and control cohorts (W = 0.642) among 3 observers. With scores of ≥2 being defined as “positive” readings indicating recognizable ischemic lesions (82/147 = 49 × 3 for the TIA cohort, and 10/108 = 36 × 3 for the control cohort), the sensitivity and specificity of the ASL CBF map in the diagnosis of TIA were 55.8% (95% CI, 0.49–0.63) and 90.7% (95% CI, 0.87–0.95), respectively (Table 2). The magnetic field strength (23 patients on 1.5T, 26 patients on 3T in the TIA cohort; 17 patients on 1.5T, 19 patients on 3T in the control cohort) was not associated with a significant difference in mean reading scores of ASL CBF maps (t test). In the TIA cohort, 44 (89.8%) of 49 patients presented with hemispheric symptoms, such as focal weakness and aphasia. In this subgroup of patients with hemispheric TIA and positive ASL CBF map readings (score ≥ 2), 93.3% (70/75 positive readings) of the cases showed brain regions where the hypoperfusion identified matched the laterality of the neurologic symptoms at TIA onset. In the rest of the observations (5/75), hyperperfusion was characterized in brain regions corresponding to transient neural deficits during the TIA attacks.

DISCUSSION

The widespread adoption of newer advanced MR imaging, such as DWI, has significantly improved the characterization of ischemic lesions in patients with TIA. However, the diagnosis of TIA in a substantial proportion of cases remains purely clinically based, as no corroborating imaging findings exist by standard MR imaging. Therefore, it would be of potential value to identify imaging technologies with a high sensitivity for the detection of minor cerebral perfusion abnormalities, to more confidently establish the diagnosis of TIA in clinical practice. ASL has emerged as such an imaging technique with a purported high sensitivity for the detection of perfusion abnormalities in both TIA and acute stroke.18-20,23 In our current study, we explored the value of ASL in the detection of perfusion deficits in a cohort of clinically diagnosed patients with TIA with unremarkable standard MR imaging results. To avoid confounding factors that are known to produce positive findings on ASL images, we excluded patients with a history of stroke and those with any brain lesions that can be identified on DWI and MRA sequences. As a preliminary investigation of the value of ASL in TIA, our current analysis was limited by small study size and discrepancy in the sex ratio between TIA and control cohorts (Table 1). The power of the study was further affected by the gap in the median age of the TIA and control cohorts (70.7 years and 61.4 years, respectively), though there was no significant difference in the mean age of the patient cohorts (65.6 years and 60.2 years, respectively; P > .05, t test).

We found that ASL provided imaging evidence of disturbed perfusion (this study focused on hypoperfusion) in 55.8% of imaging-negative TIA cases, as judged by the standard imaging protocols including DWI and MRA. ASL CBF map reading also showed a high specificity (90.7%) for abnormal perfusion in our patient cohort. Positive ASL CBF map readings showed that the location of the hypoperfusion was consistent with the neurologic symptoms at TIA onset in 93.3% (70/75) of the total observations. These findings support the hypothesis that ASL is a feasible and practical method for detection of perfusion abnormalities, with good sensitivity in patients with a clinical diagnosis of TIA. The evaluation of ASL CBF maps demonstrated good agreement in reading scores from 3 observers (W = 0.812 for TIA and W = 0.642 for control), suggesting that ischemic lesions in ASL CBF maps could be consistently recognized by different readers, and thus supporting the conclusion that ASL has good reliability as well. In practice, ASL has the advantages of being contrast-free and requiring a relatively short scan time (< 4 minutes in our protocol), which may allow this technique to be widely used in the clinical management of TIA and other clinical emergencies that mimic it.
Prospective studies have shown a high risk for stroke within the immediate hours and days after TIA. In our current study, we followed up on the TIA cohort for an average period of 1 year (range, 164–538 days), and none of the patients experienced a post-TIA stroke. The reported factors correlating with the risk for post-TIA stroke include ABCD/ABCD² scores, and positive MR imaging findings on DWI and MRA. As a clinical score based on the presence of pre-existing conditions to determine the risk for stroke after a TIA, the value of ABCD/ABCD² scores in the prediction of post-TIA stroke risk have been controversial and vary greatly by patient cohort and clinical protocol. Our TIA cohort had a high median ABCD² score of 4; however, none of the patients appeared to have a stroke during the average 1-year follow-up period, though silent infarcts could have gone undetected (as patients had routine clinical follow-up but no additional MR imaging).

The lack of clinically evident strokes in our TIA cohort may be surprising, but it may suggest that the negative standard imaging being used as a criterion for study inclusion could be associated with reduced stroke risk. Although the power of the current analysis was limited by a relatively small cohort size, we found that patients with TIA with positive findings on DWI and MRA are more likely to display readable abnormalities on ASL than imaging-negative cases used in the current study (data not shown), raising the question of whether ASL data should be included in criteria for the evaluation of stroke risk after TIA onset. Better characterization of such a patient cohort may help to clarify the value of ABCD/ABCD² scores in the prediction of post-TIA stroke. Specifically, future studies of much larger sizes will be necessary to determine stroke risks in these patient groups: those with TIA with MR imaging abnormalities (including DWI and MRA), those with TIA with ASL abnormalities only, and those with TIA with no MR imaging or ASL abnormalities.

Low SNR and low spatial resolution are major limitations of ASL. The SNR is directly proportional to voxel size and the PLD time, which is defined as the duration between labeling of the spins and acquisition of the images, and is typically between 1.5 and 2.0 seconds. Longer PLDs (>2 seconds) could help to improve CBF quantification, however, at the cost of a further decrease in SNR. In the current analysis, a single PLD of 2.0 seconds was used, resulting in the detection of focal hypoperfusion in 55.8% of imaging-negative patients with TIA. Considering the universal existence of multiple conditions in patients with TIA that related to vascular pathogenesis, arterial transit time (ATT) could vary greatly among individual patients. Therefore, calculated CBF map on the basis of a single PLD might not be the best approach to accurately reflect the perfusion status in these patients. In this case, an option would be to obtain images at multiple PLDs and calculate ATT-adjusted CBF maps, aiming to improve the sensitivity in the detection of minor perfusion changes in patients with TIA.

CONCLUSIONS
Our results suggest the potential value of ASL perfusion data in the detection of abnormalities in patients with TIA, which may help improve the diagnostic certainty in otherwise imaging-negative patients with TIA.
