Spontaneous Delayed Migration/Shortening of the Pipeline Embolization Device: Report of 5 Cases

ABSTRACT
SUMMARY: Five patients were found to have spontaneous delayed migration/shortening of their Pipeline Embolization Devices on follow-up angiography. The device migrated proximally in 4 patients and distally in 1 patient. One patient had a subarachnoid hemorrhage and died as a result of migration of the Pipeline Embolization Device, and another patient presented with complete MCA occlusion and was left severely disabled. Mismatch in arterial diameter between inflow and outflow vessels was a constant finding. Migration of the Pipeline Embolization Device was managed conservatively, with additional placement of the device, or with parent vessel occlusion. Obtaining complete expansion of the embolization device by using a longer device, increasing vessel coverage, using adjunctive aneurysm coiling, and avoiding dragging and stretching of the device are important preventive measures. Neurointerventionalists should be aware of this potentially fatal complication and take all necessary preventive measures.

ABBREVIATIONS: PED = Pipeline Embolization Device; SHA = superior hypophyseal artery

The Pipeline Embolization Device (PED; Covidien/ev3, Irvine, California) is a dedicated flow diverter designed to treat intracranial aneurysms. Recent series have shown the PED to be a reasonably safe and effective treatment.1-5 The risks for intracranial hemorrhage, delayed aneurysm rupture, and thromboembolic events have been major concerns with this approach.1,3,6,7 Additional complications are becoming evident, as the PED is increasingly used for an expanding population of patients with cerebral aneurysms. In this study, we report 5 cases of patients with spontaneous delayed migration or shortening of the PED and discuss the possible cause, implications, and management of this serious and potentially fatal complication.

MATERIALS AND METHODS
Five patients treated with the PED in whom spontaneous delayed migration or shortening of their devices developed were prospectively identified. During the same period (from November 2010–January 2013), a total of 155 patients were treated with the PED at our institution. The 5 cases of PED migration occurred late during the study period (second half of the cohort).

PEDs were deployed through a Marksman microcatheter (ev3, Irvine, California) by use of a triaxial guide-catheter system. The maximal diameter in the predicted landing zone was determined, and the PED was sized according to the width of the inflow vessel to avoid any endoleak. The expansion of the PED was documented under fluoroscopy or with additional DynaCT angiography (Siemens, Erlangen, Germany) at the operator’s discretion.

Representative Case Patients
Patient 1. A 50-year-old man with schizophrenia presented with an unruptured left MCA (M1) aneurysm discovered during work-up for severe cervical myelopathy. The aneurysm measured 12.7 × 11.6 mm; the diameter of the inflow vessel was 3.2 mm, and the diameter of the outflow vessel was 2.5 mm. Given the aneurysm size, wide-neck morphologic feature, and the patient’s categoric refusal of open surgery, the decision was made to treat the aneurysm with the PED. The patient was pretreated with aspirin and clopidogrel for 10 days. The patient was given a bolus of heparin, and activated clotting time was maintained at 2–3 times the baseline throughout the procedure. With use of a triaxial system, a 3 × 16-mm PED was deployed across the neck of the aneurysm, extending from the proximal superior division of the M2 segment to the mid-M1 segment (Fig 1). A control cerebral angiogram was performed and showed stasis within the aneurysm. Five months later, the patient presented to the emergency
department with an acute onset of right-sided hemiplegia. He had not been compliant with the antiplatelet therapy. A noncontrast head CT scan result was negative for hemorrhage, and CT angiography demonstrated complete occlusion of the M1. CT perfusion revealed a large area at risk, and the patient was transferred to the angiography suite for mechanical thrombectomy. A left ICA injection showed that the M1 segment of the MCA was completely occluded. It is interesting to note that the PED had migrated distally, with the proximal end of the device now within the aneurysm sac. There was no evidence of filling of the aneurysm. The procedure was aborted at this point because it was felt that blind navigation through the aneurysm sac would carry a high risk for aneurysm perforation. The patient remained hemiplegic and was discharged to rehabilitation.

**Patient 2.** A 46-year-old woman presented to our institution with a 1-year history of visual loss. A visual field test revealed right-sided homonymous hemianopsia, and MRA showed a giant left supraclinoid ICA aneurysm. Flow diversion was thought to be the most durable treatment of the aneurysm. The patient was premedicated with aspirin and clopidogrel (Plavix). On DSA, the aneurysm measured 2.8 × 2.3 cm with no distinct neck; the inflow zone was slightly distal to the ophthalmic artery, and the outflow zone was posterolateral within the aneurysm. There was delayed filling of the anterior and middle cerebral arteries caused by aneurysmal blood steal. A 4.25 × 30-mm PED was deployed from the mid-M1 segment (diameter, 1.9 mm) to the proximal cavernous ICA (diameter, 3.8 mm) (Fig 2). Control angiography showed significant contrast stasis in the entire aneurysm with excellent filling of the ante-
eventful treatment of her aneurysm with the PED (Fig 4). There was significant mismatch in arterial diameter (> 1 mm) between the inflow and outflow vessels. At 5 months after the procedure, the patient’s symptoms recurred. On the 6-month follow-up angiography, there was proximal PED migration, with the distal end of the device projecting directly into the aneurysm and creating a jet of contrast against the aneurysm sac. A second, overlapping PED was successfully deployed within the first PED to cover the neck of the aneurysm. Six weeks later, the patient’s symptoms had completely resolved and a follow-up CT angiogram showed complete obliteration of the aneurysm.

**Patient 5.** A 71-year-old woman presented for treatment of a symptomatic aneurysm of the left cavernous ICA measuring 16.5 mm. The diameter of the inflow vessel was 4.4 mm, and the diameter of the outflow vessel was 4.2 mm. It was decided to treat the aneurysm with flow diversion. A 4.5 × 18-mm PED was deployed across the aneurysm without difficulty, extending from the immediate pregenu portion to the midvertical segment of the cavernous ICA. A control angiogram demonstrated contrast stasis within the aneurysm, with adequate stent apposition to the vessel wall. A subsequent angiogram 1 day later showed complete occlusion of the aneurysm. The postoperative course was uneventful, and the patient was discharged neurologically intact. She remained asymptomatic and returned 7 months later for follow-up angiography. On DSA, there was complete filling of the aneurysm sac and the PED had migrated proximally. The migration distance was 7.5 mm. A second, overlapping 5 × 30-mm PED was subsequently deployed beyond the first stent to bridge the neck of the aneurysm and disrupt the inflow jet.
Several groups have recently reported their experience with the PED. In most series, remarkably high rates of aneurysm occlusion were achieved at follow-up with an acceptable risk for major complications. Some authors, based on favorable results from non-controlled series, have even recommended the PED as a first-line option for unruptured aneurysms. Long-term safety results, however, are lacking and new complications have been emerging as neurointerventionalists accumulate experience with the device. The phenomenon of delayed migration or shortening of the PED has not been described in previously published series.

In this study, we have reported 5 cases of patients with spontaneous delayed migration or shortening of the PED (Table). In most cases, the PED migrated proximally (patients 2–5), and there was a significant difference in luminal diameter between inflow and outflow vessels. This may have produced a constant retrograde squeezing force at the distal end of the PED causing it to “watermelon-seed” backward into the aneurysm sac. Also, given the vertical position of the ICA, the weight of the device may have dragged the construct downward. The PED migration may also be at least in part the result of an “accordion effect,” a phenomenon of spontaneous migration because it is a low-porosity stent, which facilitates the transmission of a force exerted at one end of the device to the other end.

The PED is particularly vulnerable to the phenomenon of spontaneous migration because it is a low-porosity stent, which facilitates the transmission of a force exerted at one end of the device to the other end. The migration of the PED is somewhat similar to the migration of Enterprise stents. Previous cases have involved Enterprise stents deployed from the midbasilar artery to the P1 segment of the posterior cerebral artery during treatment of basilar tip aneurysms. The migration was primarily attributed to the diameter difference between the basilar artery and the P1 segment of the posterior cerebral artery. Lubicz et al previously described the delayed migration of a Silk stent (Balt Extrusion, Montmorency, France) in a patient with a giant saccular carotid ophthalmic aneurysm. The patient had a massive SAH as a result of the migration and died.

Our present series shows that PED migration can occur both early and late after treatment. In patient 2, the migration occurred within 72 hours. Conversely, in patient 4 the migration likely occurred several months after the initial intervention, as suggested by the recurrence of the patient’s symptoms at 5 months.

Although PED migration was uneventful in 3 patients, it was associated with fatal or severely disabling complications in 2 patients. In patient 2, the distal end of the PED migrated proximally into the aneurysm sac, creating a direct jet of blood against the aneurysm wall and precipitating aneurysm rupture. This occurrence is further supported by the observation that the rupture site on the aneurysmal dome was directly facing the distal end of the device. In patient 1, the patient presented with complete occlusion of the MCA, but it is not clear whether this event was related to the distal migration of the PED. Still, the device migration into the aneurysmal sac precluded any attempt at mechanical thrombolysis, and the procedure had to be aborted because of the high risk for iatrogenic aneurysm perforation (thus preventing potential neurologic recovery).

The following precautions should be taken to minimize the occurrence of spontaneous delayed PED migration or shortening, especially if there is a mismatch in diameter between inflow and outflow vessels:

1. Obtaining complete expansion of the PED with optimal vessel wall apposition. Accurate sizing of the PED is of utmost importance. DynaCT may be useful to confirm adequate apposition of the device to the vessel wall.
2. Using longer PEDs to prevent excessive foreshortening. In addition, the conveyance of retrograde forces is lower with longer stents. Increasing vessel coverage proximally and/or distally to the aneurysm may also be helpful. A second stent can be deployed to increase vessel coverage when needed. One could
argue in retrospect that PED deployment was too proximal in patients 3 and 5 and was too distal in patient 1.
3. Avoidance of dragging of the PED to prevent foreshortening. Instead of going in distally and dragging the device proximally into the landing zone, it would be preferable to go directly into the landing zone to detach and deploy the device.
4. Avoidance of stretching of the PED during deployment to prevent the “accordion effect.”
5. Adjunctive aneurysm coiling, as this may prevent prolapse of the PED into the aneurysm for larger aneurysms.

We have recently applied these precautions, and we will assess in a future study whether they can lead to a significant decrease in the incidence of PED migration or shortening.

PED migration is best managed by placing additional PEDs to achieve complete coverage of the aneurysm and divert the blood flow away from the aneurysmal sac. A J-shaped guidewire is passed through the migrated stent and is navigated directly into the distal ICA. This is followed by deployment of 1 or more PEDs as necessary until the parent vessel is reconstructed. If the proximal part of the device has migrated into the aneurysmal sac and attempts to recatheterize the PED have failed, retrograde access of the PED is gained from the distal ICA through a microwire advanced from the basilar artery through the posterior communicating artery or from the contralateral ICA through the anterior communicating artery. Endovascular parent vessel reconstruction or surgical ligation, when tolerated, is an alternative strategy to manage PED migration. In the setting of subarachnoid hemorrhage, as in patient 2, the goal of treatment is to obtain immediate occlusion of the aneurysmal sac and/or the parent vessel.

CONCLUSIONS
Spontaneous delayed migration or shortening of the PED is a serious and potentially fatal complication. The device may migrate proximally or distally and result in aneurysmal rupture or thrombotic events. The migration may occur both early and late after treatment. Obtaining complete expansion of the PED by using longer PEDs, increasing vessel coverage, using adjunctive aneurysm coiling, and avoiding dragging and stretching of the PED are important preventive measures. Neurointerventionalists should be aware of this undesirable phenomenon and take all necessary preventive measures. If any concern arises regarding the position of the PED, early imaging follow-up may be indicated.
