Structural Abnormalities in Patients with Insular/Peri-insular Epilepsy: Spectrum, Frequency, and Pharmacoresistance

M.-C. Chevrier, C. Bard, F. Guilbert, and D.K. Nguyen

ABSTRACT

SUMMARY: Between 2002 and 2010, a total of 48 patients were seen at our epilepsy clinic with insular/peri-insular cortex epilepsy. Review of their MR imaging scans revealed a neoplastic lesion in 27% of patients, a malformation of cortical development in 21%, a vascular malformation in 19%, and atrophy/gliosis from an acquired insult in 17%. MR imaging results were normal in 4 patients. Other miscellaneous findings included a case of Rasmussen encephalitis, a nonspecific insular millimetric T2 signal abnormality, a neuroepithelial cyst, and hippocampal sclerosis without MR imaging evidence of dual insular pathologic features (despite depth electrode–proven insular seizures). Refractoriness to antiepileptic drug treatment was present in 56% of patients: 100% for patients with malformations of cortical development (1.0; 95% CI, 0.72–1.0), 50.0% (0.5; 95% CI, 0.21–0.78) in the presence of atrophy/gliosis from acquired insults, 39% (0.39; 95% CI, 0.14–0.68) for neoplastic lesions, and 22.2% (0.22; 95% CI, 0.06–0.55) for vascular malformations.

ABBREVIATIONS: IPICE = insular/peri-insular cortex epilepsy; MCD = malformation of cortical development

For statistical analysis, patients were partitioned within 6 radiopathologic categories: 1 (neoplastic), 2 (malformations of cortical development [MCDs]), 3 (vascular malformations), 4 (atrophy/gliosis from acquired insults), 5 (other), and 6 (normal). A $2 \times 6$ contingency table was constructed partitioning patients between pharmacoresistant and responsive to medication. A Fisher exact test was performed on this $2 \times 6$ contingency table assuming that categories are mutually exclusive, followed by a Fisher exact test for each category when appropriate. A Bonferroni correction was used to control for multiplicity ($\alpha = 0.05/6$ or $\alpha = 0.008$). For each category presenting a significant association with pharmacoresistance, the risk was reported with a 95% CI. Calculations were produced on StatsDirect statistical software (version 2.7.9, http://www.statsdirect.com).

RESULTS
A total of 59 (6.4%) of 920 patients with epilepsy had IPICE. Eleven patients were excluded because MR imaging scans of 5 patients were destroyed, no MR imaging scans were taken of 2 patients because of contraindications (eg, pacemaker), and MR imaging was not available before surgical treatment in 4 patients. Hence, we retrospectively reviewed the MR imaging results of 48 patients with IPICE. Of these patients, 7 had definite IPICE, 24 had probable IPICE, and 17 had possible IPICE. The group included 21 men and 27 women with a median age of 39 years (age range, 2–73 years).

The On-line Table lists the pathologic patterns detected on MR imaging in the 48 patients and refractoriness to antiepileptic drug treatment. It disclosed neoplastic lesions in 13 patients (27%). Eight patients presented pathologic features compatible with low-grade glioma and 5 patients, with high-grade glioma. Eight patients had astrocytomas (Fig 1), 4 of which were low-grade, and 4 were high-grade. Three patients had low-grade oligoastrocytoma. MR imaging results in these patients demonstrated infiltrative masses centered over the insula with extension to the frontal and temporal lobes. One patient, who had a previously resected, low-grade oligodendroglioma, went on to have IPICE many years later in the context of insular tumor recurrence. Another patient had glioblastoma multiforme involving the insula and the temporal operculum.

MCDs were detected in 10 patients (20%). Five patients had cortical dysplasia involving the insula; 4 had polymicrogyria implicating the insula with perisylvian extension (Fig 2), including 1 patient with bilateral perisylvian polymicrogyria; and another patient had tuberous sclerosis presenting multiple cortical tubers, 1 being located in the operculoinsular region (Fig 3). Vascular malformations were found in 9 patients (19%). Four patients had an arteriovenous malformation (Fig 4) with a nidus in the insula or inducing a FLAIR signal abnormality in the insula. Three patients had a Sylvian bifurcation aneurysm with mass effect on the insular cortex, and 2 others had a cavernoma centered on the insula (Fig 5).

Atrophy/gliosis from acquired insults was observed in 8 patients (17%). Two patients had encephalomalacia and atrophy after trauma (Fig 6): one involving the temporal operculum and insula after surgical evacuation of a hematoma, and the other involving the insula and frontal and temporal opercula. One patient had signs of an old ischemic infarct exclusively in the insular cortex. Another patient had cystic encephalomalacia after herpes encephalitis affecting the insula and temporal lobes. Yet another patient had encephalomalacia and atrophy after a congenital insult, 2 patients had encephalomalacia and atrophy of indeterminate cause involving the insula and the frontal or temporal opercula, and 1 other patient had pial enhancement over the insula and frontal operculum of unknown cause.

Serial MR imaging in a patient with Rasmussen encephalitis revealed an initial insular FLAIR signal abnormality followed by unilateral fronto-temporo-insular atrophy and gliosis. A millimetric, innocuous-looking T2 signal abnormality over the posterior insula was...
found in 1 patient. A neuroepithelial cyst vs a signal abnormality in the insula was seen in another patient. One patient had no insular lesions (despite depth electrode–proven insular seizures) but rather hippocampal sclerosis (and concomitant hippocampal seizures). MR imaging results were normal in 4 patients: 2 of whom had definite IPICE, and 2 of whom had possible IPICE.

Among the 43 patients with lesions in the insula, damage was confined to the insular cortex with or without involvement of the adjacent operculum in 20 patients. More than 1 operculum was affected in the remaining 23 patients.

Refractoriness to antiepileptic drug treatment was 100% for the 10 patients with MCD (1.0; 95% CI, 0.72–1.0), 50.0% (0.5; 95% CI, 0.21–0.78) in the presence of atrophy/gliosis from acquired insults, 39% (0.39; 95% CI, 0.14–0.68) for neoplastic lesions, and 22.2% (0.22; 95% CI, 0.06–0.55) for vascular malformations. An estimated 75% of patients with normal MR imaging results (0.75; 95% CI, 0.19–0.99) had refractory epilepsy (Table 1). The patient with Rasmussen encephalitis had refractory epilepsy partialis continua with occasionally complex partial seizures.

DISCUSSION
Some epileptogenic lesions are more commonly found in certain regions of the brain. For example, typical epileptogenic lesions diagnosed in patients with temporal lobe epilepsy are hippocampal atrophy/sclerosis, dysembryoplastic neuroepithelial tumors, gangliogliomas, postherpetic encephalitic gliosis, and postransformations. An estimated 75% of patients with normal MR imaging results (0.75; 95% CI, 0.19–0.99) had refractory epilepsy (Table 1). The patient with Rasmussen encephalitis had refractory epilepsy partialis continua with occasionally complex partial seizures.

atrophy or encephalomalacia from acquired insults. Trauma and herpes encephalitis classically injure the temporal lobes, but damage may extend to the insula. Although strokes are the most common source of epilepsy in elderly people, they were not found here to be a cause of IPICE, likely because of the rare occurrence of pure insular ischemic strokes. One patient with IPICE had Rasmussen encephalitis, a chronic inflammatory disease of unknown origin affecting 1 hemisphere. Some imaging studies have previously suggested that the progressive hemiatrophy associated with Rasmussen encephalitis starts preferentially in the insula and in the perisylvian area.

Refractoriness to antiepileptic drug treatment was 100% for MCDs in the insular/peri-insular region, which is not necessarily surprising, as such entities located in other areas are generally linked with drug-resistant epilepsies as well. The refractoriness rate was 38.5% (5/13) for patients with tumors in our series, most of which were low-grade gliomas (4/5; 80%). These findings are consistent with the observations of Duffau et al, who recorded a refractoriness rate of 58% with insular low-grade gliomas and suggested that the latter are more prone to eliciting drug-resistant epilepsy than tumors invading other brain structures. Although half (2/4) of patients with IPICE related to atrophy/gliosis had drug-resistant seizures, their low number did not allow further interpretation. Although some studies have reported a high rate of drug-resistant seizures in posttraumatic or postencephalitic epilepsies, epilepsies after strokes usually respond to medical treatment. Of interest, 1 patient with a millimetric T2 signal abnormality in the posterior insula (initially dismissed as nonspecific), 1 patient with hippocampal sclerosis but no insular lesion, and 3 of 4 patients with normal MR imaging results had refractory insular seizures confirmed by invasive recordings. This finding raises the possibility that a certain proportion of patients with persisting seizures, despite temporal, frontal, or parietal lobe epilepsy surgeries, might have unrecognized IPICE.

The limitations of our study are inherent to any retrospective design. Because MR imaging scans were not standardized (magnet strength, acquisition protocols), anatomic delineation of insular involvement was constrained in some cases. Coronal and sagittal T2-weighted sequences with thin sections on the insula would certainly have increased the precision. Although the lesions were centered on the insular/peri-insular area, some extended slightly beyond, and we cannot exclude that seizures originated from adjacent lobes with rapid propagation to the insular/peri-insular area. Finally, selecting patients from a specialized epilepsy clinic in a tertiary academic center may have biased the study into finding a higher rate of lesions associated with intractable epilepsy.

CONCLUSIONS
A spectrum of structural abnormalities may evoke IPICE. In order of frequency, we noted tumors, MCDs, vascular lesions, and atrophy/gliosis from acquired insults. IPICE related to MCDs, atrophy/gliosis from acquired insults, and tumors is frequently refractory to antiepileptic drugs.
