Stent Retrievers in Acute Ischemic Stroke: Complications and Failures during the Perioperative Period

ABSTRACT

BACKGROUND AND PURPOSE: Stent retriever–assisted thrombectomy promotes high recanalization rates in acute ischemic stroke. Nevertheless, complications and failures occur in more than 10% of procedures; hence, there is a need for further investigation.

MATERIALS AND METHODS: A total of 144 patients with ischemic stroke presenting with large-vessel occlusion were prospectively included. Patients were treated with stent retriever–assisted thrombectomy ± IV fibrinolysis. Baseline clinical and imaging characteristics were incorporated in univariate and multivariate analyses. Predictors of recanalization failure (TICI 0, 1, 2a), and of embolic and hemorrhagic complications were reported. The relationship between complication occurrence and periprocedural mortality rate was studied.

RESULTS: Median age was 69.5 years, and median NIHSS score was 18 at presentation. Fifty patients (34.7%) received stand-alone thrombectomy, and 94 (65.3%) received combined therapy. The procedural failure rate was 13.9%. Embolic complications were recorded in 12.5% and symptomatic intracranial hemorrhage in 7.6%. The overall rate of failure, complications, and/or death was 39.6%. The perioperativemortality rate was 18.4% in the overall cohort but was higher in cases of failure (45%; \(P = .003\)), embolic complications (38.9%; \(P = .0176\)), symptomatic intracranial hemorrhages (45.5%; \(P = .0236\)), and intracranial stenosis (50%; \(P = .0176\)). Concomitant fibrinolytic therapy did not influence the rate of recanalization or embolic complication, or the intracranial hemorrhage rate. Age was the only significant predictive factor of intracranial hemorrhage (\(P = .043\)).

CONCLUSIONS: The rate of perioperative mortality was significantly increased in cases of embolic and hemorrhagic complications, as well as in cases of failure and underlying intracranial stenoses. Adjunctive fibrinolytic therapy did not improve the recanalization rate or collateral embolic complication rate. The rate of symptomatic intracranial hemorrhage was not increased in cases of combined treatment.

MATERIALS AND METHODS

Patient Selection

Ethical approval for this study was obtained by the local ethics committee in our institution after review of the stroke protocol. Patients with acute stroke were examined at admission by a senior stroke neurologist who assessed the severity of the neurologic deficit by using the NIHSS. An NIHSS score equal or superior to 8 was required for mechanical thrombectomy to be considered. Patients underwent comprehensive imaging in the acute phase, with MR imaging to delineate the extent of the ischemic lesion. In cases of MR imaging contraindications, an unenhanced head CT, CTA, and CTP were carried out.

In patients with anterior circulation strokes, the ASPECT score was calculated on DWI MR imaging or CT to assess the extent of the ischemic core. Only patients with an ASPECT score of ≥5 were included, according to our institutional protocol12 and the SAMURAI (Stroke Acute Management with Urgent Risk-factor Assessment and Improvement) study.19

In accordance with our institutional stroke protocol, patients presenting within 4.5 hours from symptom onset received a combined therapy associating IV fibrinolysis (rtPA 0.9 mg/kg) and mechanical thrombectomy. Patient presenting between 4.5 and 6 hours with anterior circulation strokes or presenting with IV fibrinolysis contraindication were treated with stand-alone thrombectomy. For patients with posterior circulation strokes, a combined therapy associating IV fibrinolysis (rtPA 0.9 mg/kg) and mechanical thrombectomy was considered only if immediate restenosis of the target artery associated with immediate reocclusion occurred. In these cases, a Wingspan stent (Boston Scientific, Minnetonka, Minnesota) was inserted through a sheath into the dominant, or navigable, vertebral artery. A 0.021-inch internal diameter microcatheter (Prowler Select Plus [Codman & Shurtleff] or Vasco 21 [Balt, Montmorency, France]) was navigated distal to the point of occlusion over a 0.014-inch steerable microwire. A microcatheter angiographic run was then carried out to define the vascular bed distal to the thrombus. The stent retriever was then introduced through the microcatheter and the device deployed across the occluding thrombus. The microcatheter distal marker was positioned at the exact level of the proximal marker of the stent retriever. After deployment, the stent retriever was maintained in place for approximately 3–7 minutes to allow full device expansion. The stent retriever was fully deployed in all cases. An angiographic run was performed to evaluate the degree of temporary recanalization. The fully deployed stent retriever and the delivery microcatheter were then gently pulled back together and recovered through the guiding catheter. During the retrieval, the BGC was inflated to interrupt anterograde flow. Manual aspiration with a 50-mL syringe was performed through the hemostatic valve during the retrieval to reverse the flow and to aspirate clot debris possibly lost in the guide catheter lumen. The integrity of the stent was consistently checked following each pass.

Successful recanalization was defined as TICI 2b or 3.23 If the vessel was not reopened to at least TICI 2b with a maximum of 5 passes, then the treatment was considered failed. All TICI scores were independently reviewed by a second neuroradiologist and adjudicated in cases of disagreement. Neither IV heparin nor intra-arterial fibrinolytics were administered at any time during the procedure, even if the recanalization attempt was unsuccessful. Groin punctures were routinely closed with an Angio-Seal (St. Jude Medical, Minnetonka, Minnesota).

Should intracranial stenosis occur, complementary stand-alone angioplasty was preferred with use of a Gateway balloon (Stryker), or an UltraFlow balloon (Covidien) 2.5 mm. Inflation was cautiously done up to 6 atm. Following an angiographic control, stent placement was considered only if immediate restenosis of the target artery associated with immediate reocclusion occurred. In these cases, a Wingspan stent (Boston Scientific, Natick, Massachusetts) was chosen and sized according to the target vessel size. Antiplatelet management consisted of 500 mg of aspirin IV during the procedure, and double antiplatelet was discussed after the 24-hour CT control in view of any serious hemorrhagic complications.

Adverse Event Definition

The types of hemorrhagic complications were defined according to the European Co-operative Acute Stroke Study-II (ECASS II).34 Symptomatic ICH was defined as parenchymatous hemorrhage (PH)1 or PH2 hematomas and a ≥4-point NIHSS score decline or death within the periprocedural period.

Embolic complications were defined as an angiographic occlusion in a previously unaffected vascular territory observed on the angiogram after clot removal and associated with new lation, an 8F or 9F Merci balloon-guided catheter (BGC; Concentric Medical) was inserted through a sheath. For the posterior circulation, a 6F Envoy guiding catheter (Codman & Shurtleff) was placed through a sheath into the dominant, or navigable, vertebral artery. A 0.021-inch internal diameter microcatheter (Prowler Select Plus [Codman & Shurtleff] or Vasco 21 [Balt, Montmorency, France]) was navigated distal to the point of occlusion over a 0.014-inch steerable microwire. A microcatheter angiographic run was then carried out to define the vascular bed distal to the thrombus. The stent retriever was then introduced through the microcatheter and the device deployed across the occluding thrombus. The microcatheter distal marker was positioned at the exact level of the proximal marker of the stent retriever. After deployment, the stent retriever was maintained in place for approximately 3–7 minutes to allow full device expansion. The stent retriever was fully deployed in all cases. An angiographic run was performed to evaluate the degree of temporary recanalization. The fully deployed stent retriever and the delivery microcatheter were then gently pulled back together and recovered through the guiding catheter. During the retrieval, the BGC was inflated to interrupt anterograde flow. Manual aspiration with a 50-mL syringe was performed through the hemostatic valve during the retrieval to reverse the flow and to aspirate clot debris possibly lost in the guide catheter lumen. The integrity of the stent was consistently checked following each pass.

Successful recanalization was defined as TICI 2b or 3.23 If the vessel was not reopened to at least TICI 2b with a maximum of 5 passes, then the treatment was considered failed. All TICI scores were independently reviewed by a second neuroradiologist and adjudicated in cases of disagreement. Neither IV heparin nor intra-arterial fibrinolytics were administered at any time during the procedure, even if the recanalization attempt was unsuccessful. Groin punctures were routinely closed with an Angio-Seal (St. Jude Medical, Minnetonka, Minnesota).

Should intracranial stenosis occur, complementary stand-alone angioplasty was preferred with use of a Gateway balloon (Stryker), or an UltraFlow balloon (Covidien) 2.5 mm. Inflation was cautiously done up to 6 atm. Following an angiographic control, stent placement was considered only if immediate restenosis of the target artery associated with immediate reocclusion occurred. In these cases, a Wingspan stent (Boston Scientific, Natick, Massachusetts) was chosen and sized according to the target vessel size. Antiplatelet management consisted of 500 mg of aspirin IV during the procedure, and double antiplatelet was discussed after the 24-hour CT control in view of any serious hemorrhagic complications.

Adverse Event Definition

The types of hemorrhagic complications were defined according to the European Co-operative Acute Stroke Study-II (ECASS II).34 Symptomatic ICH was defined as parenchymatous hemorrhage (PH)1 or PH2 hematomas and a ≥4-point NIHSS score decline or death within the periprocedural period.

Embolic complications were defined as an angiographic occlusion in a previously unaffected vascular territory observed on the angiogram after clot removal and associated with new
ischemic changes on 24-hour postprocedural CT or MR imaging.

All 24-hour CT/MR imaging scans were reviewed by a second neuroradiologist and adjudicated in cases of disagreement.

Postoperative Management
A CT scan was performed at the end of the procedure to screen for immediate hemorrhagic transformation. Airway support was immediately discontinued after the procedure to allow prompt neurologic re-evaluation. Mechanical ventilation was maintained in cases of posterior circulation stroke. No antiplatelet or heparin was administered during the first 24 hours. An additional CT or MR imaging examination was performed 24 hours after the procedure. If no hemorrhage was present, aspirin 160 mg/day was administered. The length of stay was between 2 days and 1 month. The NIHSS score was then reported at discharge by a stroke practitioner.

Statistical Analysis
Patient characteristics were presented by use of median and range for continuous variables and frequencies and proportions for categoric variables. Statistical significance between recanalization failure and success and between complications and no complications was assessed by the Pearson $\chi^2$ test for categoric variables and the Mann-Whitney U test or the Student $t$ test for continuous variables. Baseline NIHSS score was entered as a continuous variable. The significance of adding or removing a variable from the logistic model was determined by the maximum likelihood ratio test. ORs and their 95% CIs were calculated. The goodness-of-fit of the models was assessed by use of the Hosmer and Lemeshow $\chi^2$ test. A level of $P < .05$ was considered statistically significant. Statistical analysis was performed by use of SAS software, version 9 (SAS Institute, Cary, North Carolina).

RESULTS
Population
From August 2009 to November 2011, a total of 144 consecutive patients (70 women and 74 men) aged 26–91 years (median age, 70 years; mean age, 67 years) were treated. Mean baseline NIHSS score was 16.6 (median, 18; range, 3–36).

Acute MR Imaging
MR imaging was performed in 142 of 144 patients. Two patients had contraindications to MR imaging and were assessed by CT, CTA, and CTP. The mean DWI-derived ASPECT score was 6.3 (range, 3–10). In 109 patients (75.7%), the occlusion involved the anterior territory: MCA in 60 patients, ICA in 10 patients, ICA termination in 23 patients, and tandem occlusion in 16 patients. Acute occlusion of the basilar artery (BA) was noted in 35 patients (24.3%).

Protocol Deviation
Protocol deviations were observed in 18 cases (12.5%). Seven patients with an NIHSS score < 8 were included: 3 cases of a symptomatic BA occlusion and 4 cases of pertinent motor deficit in the anterior circulation. Eleven patients were treated despite an ASPECT score < 5. Among these patients (7 patients from the combined group, 4 from the stand-alone thrombectomy group), 3 (21.4%) underwent hemorrhagic transformation, from which 2 (18.2%) were symptomatic.

Failure Rate
We noted 6 cases of TICI 2a (4.9%), 1 case of TICI 1 (0.7%), and 13 cases of TICI 0 (9%), which corresponds to an observed total failure rate of 13.9%. In our study, the mortality rate in failed thrombectomy cases (45%) was significantly higher than in the overall cohort (18.4%; $P = .003$). The overall rate of successful recanalization was 86.1% (TICI 3: 69.4%; TICI 2b: 16.7%).

Embolic and Hemorrhagic Complications
Embolic complications were observed in 18 patients (12.5%): 8 embolic complications (44.4%) were observed in the stand-alone thrombectomy group and 10 (55.6%) in the combined group ($P = .534$) (Table and On-line Table). When the clot was removed from the anterior circulation (MCA or ICA), we reported distal emboli within the anterior cerebral artery territories (6 cases) (Fig 2), distal M3-MCA (3 cases), and posterior cerebral arteries (3 cases). When the clot was removed from the BA, embolic complications were observed within the posterior inferior cerebellar artery (3 cases), the posterior cerebral arteries (2 cases), and the superior cerebellar artery (2 cases). Thirteen patients (72.2%) had clinical worsening including 7 deaths (38.9%), whereas the overall rate of periprocedural mortality was 18.4% ($P = .0176$). Overall hemorrhagic complications were noted in 30 cases (20.8%): 9 (18%) in the stand-alone thrombectomy group and 21 (22.3%) in the combined group ($P = .541$). We identified 4 subarachnoid hemorrhages, 6 hemorrhagic infarcts category 1 (HI1), 3 HI2, 9 PH1, and 8 PH 2 (Fig 1) according to the ECASS II classification.

Eleven patients (7.6%) had symptomatic ICH: 6 patients from the combined group and 5 patients from the stand-alone thrombectomy group. All ICHs were observed in the initial stroke territory. In our study, the mortality rate in patients with symptomatic ICH was 45.5% ($P = .0236$).

Other Periprocedural Complications
Technical complications were reported in 5 patients. In 1 patient, an in-stent thrombosis occurred 6 hours after stent deployment for an MCA dissection secondary to MCA stenosis angioplasty, resulting in clinical worsening. An iatrogenic extracranial ICA dissection resulted in an ICA occlusion, with the patient remaining asymptomatic because of good collaterals from the circle of Willis. An arterial perforation was reported in 1 patient, who died subsequently. This perforation was not caused by the thrombectomy device but, instead, by an MCA complementary angioplasty. Device fracture and spontaneous release of the stent retriever were also seen in 2 patients. In both cases, the device was left in place.
and the patient received long-term antiplatelet therapy with a good neurologic outcome at discharge.

No death or transfusion was related to groin puncture hematoma.

The rate of overall complications (including embolic complications, symptomatic ICH, and periprocedural complications) was 18.1%. The cumulative rate of failure, complication, and/or death during the perioperative period was 39.6%. Sixteen patients (11.8%) died without procedural complications and 9 (6.6%) secondary to a procedure-related event.

**Intracranial Stenosis**

Eight cases (5.5%) of intracranial stenosis were observed, including 3 stenoses of the BA and 5 of the MCA. The mean age of the intracranial stenosis patients was 74.4 years (age range, 55–86 years). In the elderly population (>70 years old), the overall mortality rate was 24.2%, and the mortality rate related to intracranial stenosis in this subgroup was 18.8%. Unsuccessful recanalization was observed in 7 (87.5%) of 8 cases. Angioplasties were performed in 3 of 7 cases of intracranial stenosis and provided a TICI 2b–3 recanalization in 1 case. Additional deployment of an intracranial stent was performed in 1 case of intracranial stenosis with an acute in-stent thrombosis 3 hours postprocedure. Periprocedural complications were reported in 28.6% of cases and were related to complications of angioplasty (1 dissection and 1 arterial rupture). The mortality rate in cases of intracranial stenosis was 50%.

**Clinical Evaluation at Discharge**

A total of 136 patients were assessed by a stroke practitioner at discharge. Mean NIHSS score at discharge was 7.9 (range, 0–25) in the overall cohort vs 10.7 in cases of embolic complications and 14.2 for hemorrhagic complications. In cases of thrombectomy failure, the mean NIHSS score was 14.6; in patients with intracranial stenosis, it was 16.3. At discharge, 25 deaths (18.4%) were reported (Table).

**DISCUSSION**

Recent studies (IMS III, SYNTHESIS, MR RESCUE trial) did not observe superiority of endovascular approaches compared with standard intravenous rtPA treatment for large-vessel occlusion. However, these studies were conducted with first-generation devices, with almost no stent retriever. As recent studies have reported, there is a significant superiority of stent retriever devices compared with “non-stent retriever” devices from a clinical and technical point of view.

Hence, the results from these trials have not changed our current treatment protocol and practice, and we are pending the results of further trials such as THRACE (Trial and Cost Effectiveness Evaluation of Intra-arterial Thrombectomy in Acute Ischemic Stroke), SWIFT PRIME (Solitaire FR as Primary Treatment for Acute Ischemic Stroke), MRCLEAN (Endovascular treatment for acute ischemic stroke in the Netherlands), and PISTE (Pragmatic Ischaemic Stroke Thrombectomy Evaluation).

**Recanalization Failure**

The recanalization failure rate observed (13.9%) was roughly similar to the recent stent retriever literature (mean rate, 10.3%; range, 0%–33.3%). It is not clear to date if IV and intra-arterial therapies are synergistic in achieving a higher recanalization rate.

In our study, IV thrombolysis were used in combination with mechanical thrombectomy in 65.3% of patients. In this group, the
Recanalization failure rate was 14.9% vs 12% in patients treated by stand-alone thrombectomy \((P/H11005.615)\). This result suggests that IV therapy did not significantly influence the recanalization rate in acute thrombectomy cases by using a stent retriever. In a similar fashion, Dávalos et al\(^{13}\) did not report any statistically significant difference between patients treated with combined therapy compared with the stand-alone group (failure rate, 14% vs 19%). On the contrary, Dorn et al\(^{14}\) observed that the recanalization rate was higher when IV fibrinolysis was administered before mechanical thrombectomy. A reliable comparison between combined therapy and stand-alone thrombectomy is difficult to establish without a randomized trial. Actually, patients treated by stand-alone thrombectomy are selected following IV therapy exclusion criteria, resulting in a systematic selection bias. It is important to notice that the timing between these 2 therapies was not consistent and could reach several hours. In these conditions, we can hypothesize that IV therapy was not systematically fully efficient during mechanical treatment. It is interesting to note that Dávalos et al\(^{13}\) reported a significantly better 3-month outcome (mRS \(\leq 2\)) in patients treated by means of combined therapy compared with the stand-alone group, suggesting that IV therapy could play a role at a “microcirculatory level” on brain reperfusion, not visible on final DSA control.

The failure rate did not reach any statistical difference between the anterior circulation (12.3%) and the posterior circulation (17.1%) \((P = .535)\), despite the obvious anatomic difference between these 2 territories and the lack of a BGC in the posterior circulation.

**Embolic Complications**

In our study, embolic complications occurred in 18 cases (12.5%) and seemed to be a major procedural issue of the technique despite such complications being rarely reported in the recent literature. For example, Castaño et al\(^{11}\) and Roth et al\(^{18}\) did not observe any embolic complications in their first experiences. Recently, Dorn et al\(^{14}\) and Nogueira et al\(^{22}\) observed a rate of embolic complications of 3.7% and 7%, respectively. In an experimental model of cerebrovascular occlusion, authors compared 5 thrombectomy devices\(^{32}\) and concluded that the risk for embolic showers was influenced by the mechanism of action of the thrombectomy device. There was a significant increase in the number of large clot fragments with the Penumbra system (Penumbra, Alameda, California) compared with the Merci retriever. The Solitaire FR device produced larger fragments than the Waveguide system (Omnifocus Medical Technologies, Wilmington, Massachusetts). In our study, the mortality rate among patients who had embolic complications (38.9%) was higher than in the overall cohort (18.4%) \((P = .0176)\). Eleven embolic events in 109 procedures were reported in the anterior circulation (10.1%) and 7 cases (20%) among 35 procedures in the posterior circulation, with no statistical difference but a slight tendency to a higher occurrence in the posterior circulation territory \((P = .144)\), as was already suggested.\(^{12}\) In the anterior circulation, Dávalos et al reported a significant role for BGCs in decreasing the incidence of collateral infarction in the anterior circulation. In the posterior circulation, in most circumstances, the bilateral supply from the contralateral vertebral artery prevents a complete blood flow reversal. The difference in embolic complication rates between the anterior and posterior circulation may also be explained by a less efficient aspiration in BA occlusion during clot removal.

**FIG 2.** A thromboembolic occlusion of the left anterior cerebral artery after clot removal from the ipsilateral MCA. **A,** Initial DWI showing ischemic lesion in the left MCA territory (DWI ASPECT score, 7). **B,** Left ICA Townes projection angiogram showing terminal occlusion. **C,** Lateral projection angiogram after removal of the device allowing flow restoration within the MCA but embolic migration within the left anterior cerebral artery (arrow). **D,** New ischemic lesion seen on CT after the procedure within the left anterior cerebral artery territory.
No statistical differences in embolic complications were observed between the combined group and the stand-alone thrombectomy group \((P = .354)\). Adjunctive fibrinolysis was not a significant protective factor as we may have initially expected.

**Hemorrhagic Complications**

Overall hemorrhagic complications occurred in 20.8% of patients, and symptomatic ICH was reported in 7.6% of patients. This rate (7.6%) was roughly similar to the recent stent retriever literature (mean rate, 8.7%; range, 0%–20%).15,20,22,28–31 The rate was only 4% in the Solitaire retrospective multicenter study.15 In our study, the mortality rate in the symptomatic ICH subgroup was significantly higher than in the overall cohort (45.5% vs 14.9%; \(P = .0236\)). It is not surprising that age was associated with an increased risk for ICH. Mean age in the hemorrhagic group was 72 years (median age, 74.5 years; age range, 40–89 years) vs a mean age of 66 years (median age, 68.5 years; age range, 26–90 years) in patients without hemorrhagic complication \((P = .043)\). As observed in previous IV fibrinolysis studies,33–36 age seemed to be an independent predictor of ICH in our series. ICH was not significantly different between the stand-alone and combined thrombectomy groups \((P = .615)\) suggesting that IV lytics did not promote an increased rate of ICH. Time lapse from symptom onset to successful recanalization was also not related to hemorrhagic transformation, possibly because patient selection was carried out by use of DWI MR imaging, hence excluding large brain infarction.

Initial infarct size and volume measured on DWI MR imaging were reported as independent factors associated with hemorrhagic transformation in acute ischemic stroke.10,36,37 Actually, in our study, among 11 patients who had a DWI ASPECT score \(< 5\), 3 (27.3%) had hemorrhagic complications, and 2 (18.2%) were symptomatic vs only 7.6% in the overall series \((P = .651)\).

**Intracranial Stenosis**

In previous stent retriever thrombectomy studies,11–17 intracranial stenoses were not discussed. In our series, intracranial stenoses were observed in 5.5% of patients and were linked with a high mortality rate (50%). The death rate in this subgroup of patients was significantly higher than in the overall cohort (18.4%; \(P = .0176\)) and may be related to a substantial number of failed recanalizations (87.5%) and periprocedural complications (28.6%). Multiple procedural clot removal attempts in such cases may further disrupt an instable plaque and irreversibly damage the vessel wall. Nowadays, MR imaging or CTA could easily detect intracranial stenosis when arteries remain permeable14–16 but are still insufficient in diagnosing an underlying intracranial stenosis when the vessel is occluded.

**Study Limitations**

We acknowledge that our results need to be cautiously interpreted because they were derived from a single-center clinical experience. As with all continuous, prospectively collected clinical data, protocol deviations were observed (12.5%) but were reported in the study (DWI-derived ASPECT score and NIHSS inclusion). Also, interpretation of the angiographic and MR imaging results, though systematically carried out by 2 experienced neuroradiologists, were not analyzed by an independent core laboratory.

**CONCLUSIONS**

In this single-center prospective stent retriever study, recanalization failure was reported in 13.9% of patients. Embolic and symptomatic hemorrhagic complications were observed in 12.5% and 7.6%, respectively. The cumulative rate of failure, complication, and/or death was 39.6%. Mortality rate was 38.9% in cases of embolic events, 45.5% in cases of symptomatic ICH, and 57.1% in cases of intracranial stenosis. Age was an independent predictor of hemorrhagic complications. Concomitant fibrinolytic therapy did not influence the rates of recanalization, collateral embolic complications, or ICH occurrence.
