Decreased Infarct Volume and Intracranial Hemorrhage Associated with Intra-Arterial Nonionic Iso-Osmolar Contrast Material in an MCA Occlusion/Reperfusion Model

H. Morales, A. Lu, Y. Kurosawa, J.F. Clark, J. Leach, K. Weiss, and T. Tomsick

ABSTRACT

BACKGROUND AND PURPOSE: Infarct volume and intracranial hemorrhage after reperfusion with nonionic low-osmolar and iso-osmolar iodinated IRCM has not been previously compared. We postulated that iso-osmolar and low-osmolar iodinated contrast media exert varied effects on cerebral infarct after intra-arterial injection. We compared infarct volume and hemorrhagic changes following intra-arterial infusion of iodixanol, iopamidol, or normal saline in a rat MCA occlusion/reperfusion model.

MATERIALS AND METHODS: Infarct was induced in 30 rats by a previously validated method of MCA suture occlusion. Reperfusion was performed after 5 hours with either iodixanol (n = 9), iopamidol (n = 12), or saline (n = 9). MR images were obtained at both 6 and 24 hours after ischemia, followed by sacrifice. Infarct volume was measured with T2WI and DWI by semiautomatic segmentation. Incidence and area of hemorrhage were measured on brain sections postmortem.

RESULTS: T2WI mean infarct volumes were 242 ± 89, 324 ± 70, and 345 ± 92 mm³ at 6 hours, and 341 ± 147,470 ± 91, and 462 ± 71 mm³ at 24 hours in the iopamidol, iodixanol, and saline groups, respectively. Differences in infarct volume among groups were significant at 6 hours (P < .03) and 24 hours (P < .05). In the ioxdixanol, iopamidol, and saline groups, mean areas for cortical intracranial hemorrhage were 0.8, 18.2, and 25.7 mm²; and 28, 31, and 56.7 mm², respectively, for deep intracranial hemorrhage. The differences in intracranial hemorrhage area among groups were statistically significant for cortical intracranial hemorrhage (P < .01).

CONCLUSIONS: Intra-arterial infusion of nonionic iso-osmolar iodixanol showed reduced infarct volume and reduced cortical intracranial hemorrhage areas in comparison with nonionic low-osmolar iopamidol and saline. Our results may be relevant in the setting of intra-arterial therapy for acute stroke in humans, warranting further investigation.

ABBREVIATIONS: IA = intra-arterial; ICH = intracranial hemorrhage; IRCM = iodinated radiographic contrast material; HT = hemorrhagic transformation

Use of iodinated radiographic contrast material (IRCM) is inherent in the current diagnostic and therapeutic paradigm of stroke evaluation and therapy in humans, not only via intravenous infusion in CT angiography and CT perfusion but also via intra-arterial (IA) injection of IRCM during revascularization attempts. Data identifying CTP IRCM leakage as a predictor of subsequent hemorrhagic transformation (HT) and intracerebral hemorrhage (ICH) have accumulated. Yet IRCM deposition in the brain as a sequela of IA revascularization in humans is a frequent phenomenon, commonly but not invariably associated with HT.

Having identified relevant differences in ICH following IA infusion of nonionic low-osmolar IRCM in a rat reperfusion model, we postulated that potential clinical differences might also exist between low-osmolar and iso-osmolar IRCM with IA infusion. Therefore, we evaluated nonionic iso-osmolar IRCM (iodixanol, 290 mOsmol) versus a nonionic low-osmolar IRCM (iopamidol, 616 mOsmol) on brain infarct and ICH in a rodent MCA occlusion/reperfusion stroke model. To the best of our knowledge, similar experimental studies evaluating potential differences of IA IRCM on these parameters have not been previously reported.

MATERIALS AND METHODS
The animal protocol was approved by the University Animal Care Committee and conformed to the National Institutes of Health Guide for Care and Use of Laboratory Animals (http://grants.nih.gov/grants/olaw/Guide-for-the-care-and-use-of-laboratory-animals.pdf). Male Sprague-Dawley rats had unrestricted access to food and water and were housed with a 12-hour light-dark cycle. Throughout the study, the investigators and veterinarian staff closely monitored the rats’ health status.

This was a single blinded placebo-controlled study.

General Surgical Preparation
Thirty-four male Sprague-Dawley rats (body weight = 310.7 ± 12 g) were anesthetized with 3% isoflurane and maintained with 1.5% isoflurane in a mixture of 70% N₂ and 28.5% O₂. Rectal temperature was monitored and maintained at 37 °C. After induction of anesthesia, the animals were sutured. Thus, 3 groups were studied as follows: iso-osmolar saline group (n = 9), isosmolar IRCM group (n = 12), and saline group (n = 9).

Stroke Model and Drug Injection
A previously validated method of MCA occlusion with intraluminal suture was used. The left common carotid artery, external carotid artery, and internal carotid artery were isolated via a venous neck incision. A 3/0 monofilament nylon suture was used. The suture was inserted into the external carotid artery and advanced into the ICA until the tip occluded the junction of the MCA and anterior cerebral artery (approximately 20 mm beyond the carotid bifurcation until mild resistance was felt). The wound was closed temporarily, and the suture was kept in place for 5 hours. Rats were then re-anesthetized, and the ventral midline neck incision was again opened. Immediately after removal of the suture to allow reperfusion, a polyethylene-10 tube was placed into the external carotid artery with its tip at the ICA origin. The ICA was not directly catheterized. All animals initially received a 10-minute intraarterial saline infusion of 1 mL/kg. Next, either iodixanol (290 mOsmol/kg H₂O, Visipaque, 320 mg I/mL; GE Healthcare, Princeton, New Jersey), iopamidol (616 mOsmol/kg H₂O, Isovue, 300 mg I/mL; Bracco Diagnostics, Princeton, New Jersey), or normal saline (300 mOsmol/kg H₂O) was infused (1 mL/kg) for an additional 10 minutes. The external carotid artery was ligated, and the incisions were sutured. Thus, 3 groups were studied as follows: iso-osmolar iodixanol group (n = 9), low-osmolar iopamidol group, (n = 12), and saline group (n = 9).

Monitoring of Regional Cerebral Blood Flow
Before MCA occlusion, a small craniotomy near the vertex (5 mm lateral and 2 mm posterior to the bregma) was performed. This allowed cerebral blood flow estimation from the left MCA by using transcranial laser Doppler sonography perfusion measurements (PF-5001; Perimed, Jarfalla, Sweden) before and after MCA occlusion and after reperfusion with saline and/or IRCM infusion.

Neurologic Deficits and Mortality
Neurologic examinations at 45 minutes and 2, 12, and 24 hours after induction of ischemia were scored according to a 7-point scale modified from Zhang et al: no neurologic deficit = 0, forelimb flexion = 1, circling to the right = 2, impaired or lame forelimbs = 3 and hind limbs = 4, inability to walk = 5, and animal death = 6. Average scores were calculated for each group. Mortality was expressed as the number of rats dying within 24 hours before euthanasia divided by the number in each group × 100.

MR Imaging Protocol
We used a custom-made single-channel coil (Resonance Innovations, Omaha, Nebraska) designed to fit a rat’s head and optimized for use in a clinical 3T magnet (Signa Excite; GE Healthcare, Milwaukee, Wisconsin).

Following reperfusion at both 6 and 24 hours after ischemia, the animals were imaged in the coronal plane with the following protocol: T2WI (TR/TE: 2500/92 ms, section thickness: 2 mm, FOV: 6 cm, matrix: 256 × 256, NEX: 1), T1WI (TR/TE: 867/20 ms, section thickness: 2 mm, FOV: 6 cm, matrix: 256 × 256, NEX: 1), T2 FLAIR (TR/TE/TI: 12827/120/2250 ms, section thickness: 2 mm, FOV: 6 cm, matrix: 352 × 224, NEX: 1), gradient-recalled echo (TR/TE/flip angle: 550 ms/20 ms/20°, section thickness: 2 mm, FOV: 6 cm, matrix: 224 × 224, NEX: 2), and spin-echo DWI (b = 1000, FOV: 4 cm).

Infarct Identification and Volume Measurement
Infarct volume was measured in a randomized, blinded fashion at both 6 and 24 hours on T2WI and DWI, processed on a separate workstation with iPlan, Version 2.6 (BrainLab Software, Feldkirchen, Germany). Semiautomatic segmentation of the infarcted areas and of the entire brain was performed, and both the relative (volume of infarcted hemisphere / volume of total brain × 100) and the absolute volume were calculated.

Hemorrhage Identification and Measurement
After the 24-hour brain MR imaging, rats were sacrificed. The brain was sliced into six 2-mm coronal sections (12 faces). The sections were fixed in 4% paraformaldehyde for 15 minutes. A previously reported visual method was used to estimate the ICH area. Both sides of the section were optically scanned. The incidence of hemorrhage was first calculated as number of rats with hemorrhage/total number of rats per group, then similar calculations were made regarding a distinct location of the hemorrhage in the basal ganglia or cortex. The hemorrhagic area on each section face was measured by using the MCID imaging system (Imaging Research, St. Catharines, Ontario, Canada). Finally, the total area for the 12 faces was obtained by summation of individual areas.

Statistical Analysis
Statistical analysis was performed with the Statistical Package for the Social Sciences for Windows, Version 16.0 (IBM, Armonk, New York). All data were described as mean ± SE. The difference among the 3 groups for quantitative variables of ischemia was assessed by using a 1-way ANOVA analysis. When statistical significance was obtained in the ANOVA analysis, a post hoc analysis between each of the 2 groups was assessed by using the Fisher Least Significant Difference test. The difference among the 3 groups for qualitative variables was assessed by using the χ² test or Kruskal-Wallis test.

The distribution of the quantitative variable “hemorrhagic area” was evaluated with the 3 groups using a 1-way ANOVA analysis.
No statistically significant differences were found among groups in body weight, morphometric parameters, or physiologic parameters as measured during surgery, including body temperature (Celsius). Following occlusion before reperfusion, all animals showed hyperthermia, with similar average body temperatures (Celsius) in all 3 groups: 39.2 ± 0.9 (iodixanol), 39 ± 0.8 (iopamidol), and 39.3 ± 0.9 (saline).

CBF measured as the percentage perfusion after ischemia/before ischemia (39 ± 26%, 39 ± 17%, and 46 ± 22%) or as the percentage perfusion after IBCM/before ischemia (88 ± 14%, 90 ± 18%, and 78 ± 16%) for iodixanol, iopamidol, and saline, respectively, demonstrated no statistical difference among groups.

No statistical difference was found for the average neurologic score after 45 minutes and at 2, 12, and 24 hours among groups (3.9 ± 0.2, 3.6 ± 0.3, 3.4 ± 1, and 3.2 ± 1 in the iodixanol group; 3.7 ± 0.4, 3.5 ± 0.7, 3.9 ± 1.1, and 3.7 ± 1.3 in the iopamidol group; 4.1 ± 0.3, 3.3 ± 0.3, 4.3 ± 1.3, and 4.5 ± 1.8 in the saline group, respectively) (Kruskal-Wallis test). One animal in the iodixanol group (11%), 2 animals in the iopamidol group (17%), and 5 animals in the saline group (55%) died; 3, at 7 hours and 2 animals at 18 hours. Differences among groups for mortality were not statistically significant (exact test).

All animals developed T2 and FLAIR hyperintense signal and restricted diffusion in the MCA territory, including the basal ganglia, at 6 and 24 hours.

### RESULTS

No statistically significant differences were found among groups in absolute and relative infarct volumes at 6 and 24 hours after ischemia. Following occlusion before reperfusion, all animals showed decreased infarcted volume in the iodixanol group compared with iopamidol and saline groups. The Pearson coefficient was used to correlate infarct volume and hemorrhagic area. Statistical significance was set at $P < 0.05$.

Note: n.s. indicates not significant.
All animals showed HT, typically visualized on pathologic brain sections as macroscopic non-space-occupying red areas (Fig 3). The absolute cortical ICH in the iodixanol group was significantly smaller than that in the other 2 groups ($P < .01$) (Table 2). The incidence of cortical and deep (basal ganglia) ICH was not different among groups (exact test).

There was a positive but nonrobust linear scatterplot correlation between the MR imaging infarct volume and total hemorrhagic area on cut sections when all the groups were pooled (Pearson $r = 0.415$, $P < .023$; $r^2 = 0.17$). The correlations were positive for each group and fell into the moderate category as well: saline, $r = 0.365$, $P < .335$; iodixanol, $r = 0.449$, $P < .225$; and iopamidol, $r = 0.512$, $P < .089$ (Fig 4).

**DISCUSSION**

Both IV and IA IRCM injection may increase the permeability of the blood-brain barrier under normal conditions in animals. Theoretically, it is possible that large IV or IA doses of IRCM (as used in therapeutic revascularization procedures) may contribute to a BBB opening, edema, and HT. Following ischemia in humans, additional leakage of IRCM across the damaged BBB has been reported under a variety of circumstances. Contrast deposition during CT perfusion in the acute ischemic setting has been noted to be a marker of subsequent ICH. It remains unclear whether this is both cause and effect. Lummel et al recently constructed a nexus between hyperattenuated cerebral lesions and IRCM deposition immediately after mechanical revascularization preceded by CTA/CTP, suggesting that early hyperattenuated lesions were IRCM-volume related with a higher risk of secondary HT, but they did not find them necessarily predictive of reduced clinical functional outcome.

A variety of IRCM has been used clinically in human stroke evaluation and therapy, and IRCM differs in its effects on and potential for passage across the injured BBB. Variable passage across the BBB may modulate infarct edema and the risk of ICH. Ionic hyperosmolar IRCM (≈1200 mOsm) has been abandoned for IA use due to increased neurotoxicity compared with the low-osmolar IRCM (≈700 mOsm). Doerfler et al showed decreased infarct volume following IV nonionic low-osmolar IRCM (770 mOsm) versus ionic hyperosmolar iothalamate (2520 mOsm) in a rodent permanent occlusion stroke model, and they suggested that osmolarity, at least in part, explained the effect. Newer iso-osmolar IRCM is theoretically less cytotoxic due to lower osmolarity (similar to plasma, ≈300 mOsm), compared with low-osmolar IRCM. However, complex mechanisms other than osmolarity alone are acting as well.

IRCM effects on infarct volume and ICH may be due to osmotic, direct neurotoxic, hydrostatic, or vascular occlusive effects. The belief that IRCM hyperosmolarity is responsible for several adverse effects of IRCM via toxic ionic load conflicts with data suggesting a beneficial osmotic tonicity effect of intravascular IRCM on the extravascular, extracellular space based on molecular size. The molecule size of dimeric iodixanol (1000 d, approximately 6 times larger than mannitol) is approximately twice as large as monomeric iopamidol (500 d); it may be less...
able to traverse early damage to the blood-brain barrier to exert adverse osmotic or direct toxic effects in the extracellular space. Conversely, iopamidol may ultimately more easily traverse the damaged membrane to increase edema, rather than decrease it, by osmotic effect.

Endothelial cell morphology and function may be directly affected variably by IRCM injection, contributing to IRCM and fluid passage beyond the arterial lumen. There is conflicting evidence regarding increased neurotoxicity once the IRCM has crossed the BBB in animals and humans. Heinrich et al compared the direct cytotoxic effects of dimeric iso-osmolar and monomeric iso-osmolar IRCM on renal tubular cells in vitro and found that dimeric IRCM have stronger direct cytotoxic effects, postulating a mechanism independent from osmolarity.

Molecular chemotoxicity, related to the chemical structure of the molecule, decreases as the number of carboxyl groups decreases and the number of hydroxyl groups increases. Increasing the number of hydroxyl groups also increases the solubility of the agent, thus reducing its tendency to bind to tissues and proteins. Agents with no carboxyl groups and a number of hydroxyl groups evenly distributed around the main molecule have a reduced propensity for neurotoxicity. Iodixanol has an increased number of hydroxyl groups compared with low-osmolar IRCM.

Hydrolysis of iodixanol in vitro can produce a derivative of propylene glycol (2,3-dihydroxy-1-propylamine HOCH₂-CH(OH)-CH₂-NH₂). Propylene glycol when injected intra-arterially in an ischemic brain model of rats has been found to decrease BBB dysfunction by a “sealing” effect, with subsequent decreased permeability and infarct size. Although iodixanol has no biotransformation after intravenous injection, a similar “sealing” effect in the BBB is possible.

Clot formation and coagulation interactions by IRCM also have impact on infarct volume and ICH. Mechanisms and effects may be paradoxical, with equilibrium among thrombotic, antiplatelet, and fibrinolytic properties resulting in a dominant state, which varies among different IRCM. Specifically, iodixanol has been found to have a less thrombotic effect than iopamidol. However, no Doppler-measured CBF differences were identified postreperfusion in our animals that could reasonably explain an effect of persistent reduced blood flow on infarct volume in the iodixanol group. Even in the absence of coagulation-mediated oligemic effects, increased hemoglobin binding attributed to IRCM may exert a circulatory hypoxic effect, promoting neurotoxicity via reduced oxygen delivery to tissue.

Physical properties such as viscosity differ among IRCM and can exert a hydrostatic effect. Iodixanol has increased viscosity (11.8 cP) compared with iopamidol (4.7 cP) at 37°C. The reduced hydrostatic effect across an injured BBB may account for the reduced infarct edema volume measured compared with saline or a less viscous low-osmolar contrast. Differences in infusion duration were not encountered in our study. Higher viscosity fluid may reduce antegrade reperfusion and reduce hydrostatic infarct edema. If so, reduced viscosity-related antegrade reperfusion may represent a new therapeutic option for further exploration.

Changes in the environment, such as decreased pH or increased temperature in the hypoxic brain tissue, can cause changes in the physicochemical properties of IRCM as well. The role these differences play in our particular results is difficult to postulate.

We observed a trend toward increased mortality and worse neurologic score in the saline group compared with iodixanol and iopamidol. It is likely that significant damage of the BBB had already occurred by the time of reperfusion 5 hours after ischemia. Reperfusion itself caused an inflammatory cytotoxic effect, with increased edema and ICH. Reperfusion increases levels of reactive oxygen species, including the superoxide radical and nitric oxide. Oxidative radicals trigger activation of metallopro-
teinases, which disrupt permeability barriers and, in turn, potentiate injury to microvasculature and neural cells during ischemia and reperfusion.42,43 Larger infarcts and increased HT occur in the reperfusion of MCA occlusion compared with permanent occlusion, and metalloproteinases are particularly increased after reperfusion compared with models of permanent occlusion.12

Aquaporin-4 has been linked to the severity of infarct volume but not with HT.44 Therefore, the mechanism of HT, though linked to mechanisms affecting reperfusion, infarct volume, and edema previously discussed, might have a separate and different pathophysiological pathway after reperfusion in acute ischemic stroke in humans and animals.45

The contributions of hemorrhagic changes, typically petechial in the rat, might also increase differences in apparent, measurable secondary infarct edema. However, on the basis of our pilot work, more hemorrhagic changes were anticipated in the IRCM group, as opposed to lesser areas with iodixanol. In contrast to our pilot work, in which 37% of saline-infused and 75% of iohexol-infused rats exhibited HT, all animals in the current study exhibited HT, most frequent and voluminous in the saline and iopamidol groups. The higher percentage of ICH in all groups can be attributed to the additional burden of postreperfusion transportation, anesthesia, MR imaging, recovery, and delay before sacrifice, likely contributing to stress-induced infarct volume and HT. Nevertheless, we identified decreased HT in the iodixanol group. Thus, we might indeed be identifying a direct or indirect effect of iodixanol, whose exact mechanisms and significance remain to be clarified.

There are a number of limitations of our methods, analyses, findings, and hypotheses regarding the IRCM effect on infarct volume and ICH. First, our data for infarct volume as measured by DWI are inconclusive at 24 hours, mainly due to field inhomogeneity artifacts precluding 4 early cases from adequate evaluation. The role of ADC for prediction of HT in our population is yet to be explored further.46–48 The 5-hour time window is later than typically used in ischemic rat models. Knight et al49 reported no T2 signal changes early after reperfusion in a model of 2–4 hours of transient ischemia. Thus, the late time was chosen to guarantee maximal ischemic potential.

The large volume and concentration of prolonged IA IRCM injection was chosen not only to avoid overcoming any potential adverse effect not obvious with lower volumes but also to more closely simulate the effect of frequent, repetitive injections in the setting of prolonged occlusion, as is commonly used in human stroke intervention, in the timeframe when intervention is most typically applied and when benefits of revascularization are expected to be diminishing.

Another limitation is the lack of images before reperfusion. Any proposed protective effect of iodixanol might have been demonstrated by different rates of increase, or reduction, of infarct edema volume between prereperfusion and postreperfusion scans. With surgery performed remote from the scanner site, imaging during occlusion was impractical at this stage of investigation.

Differences in infarct volume and ICH might be attributed to inadequate MCA occlusion or reduced reperfusion effect in the iodixanol group. However, Doppler CBF showed no statistical differences among groups, with overall no indication of inadequate occlusion or differences in reperfusion. In addition, we have found spontaneous hyperthermia useful in estimating successful occlusion of the MCA territory in our model, with direct correlation between the body temperature and infarct size.50 All animals showed hyperthermia with similar average body temperatures before reperfusion in all 3 groups. Therein, we have no evidence that the infarct development before reperfusion was different in all 3 groups.

Nevertheless, further investigation with a larger number of animals could improve the consistency of late DWI measurements; if possible, MR imaging before reperfusion could help to confirm our results.

**CONCLUSIONS**

In our MCA occlusion/reperfusion rat model, iso-osmolar iodixanol perfusion demonstrated reduced infarct volume and cortical ICH area compared with both low-osmolar iopamidol and saline perfusion. The responsible mechanism for these findings is not clear. Multiple mechanisms are certainly possible, including not only physical-chemical or coagulation-related effects but also anti-inflammatory or other antitoxic effects at the BBB and/or in the brain parenchyma. Although different low-osmolar IRCM can have distinct effects in the infarcted brain, a potential direct or indirect effect of iodixanol might be postulated. Further investigation is warranted.
