Carotid Plaque Characterization Using 3D T1-Weighted MR Imaging with Histopathologic Validation: A Comparison with 2D Technique

ABSTRACT

BACKGROUND AND PURPOSE: 3D FSE T1WI has recently been used for carotid plaque imaging, given the potential advantages in contrast and spatial resolutions. However, its diagnostic performance remains unclear. Hence, we compared the ability of this technique to readily assess plaque characteristics with that of conventional images and validated the results with histologic classification.

MATERIALS AND METHODS: We prospectively examined 34 patients with carotid stenosis who underwent carotid endarterectomy by using 1.5T scanners and obtained 3D-FSE T1WI and 2D spin-echo T1WI scans. After generating reformatted images obtained from the 3D-FSE T1-weighted images, we calculated the contrast ratios for the plaques and the adjacent muscles and compared these findings with the pathologic classifications.

RESULTS: Carotid plaques were histologically classified as types VII, VIII, IV–V, or VI. With 3D-FSE T1WI, the range of contrast ratios for each classification was the following: 0.94–0.97 (median, 0.95), 0.95–1.29 (median, 1.10), 1.33–1.54 (median, 1.42), and 1.53–2.12 (median, 1.80), respectively. With 2D imaging, the range of contrast ratios for each classification was the following: 0.79–1.02 (median, 0.90), 0.88–1.19 (median, 1.01), 1.17–1.46 (median, 1.23), and 1.53–2.51 (median, 2.07), respectively. Results were significantly different among the 4 groups (P < .001). Sensitivity and specificity for discriminating vulnerable plaques (IV–VI) from stable plaques (VII, VIII) were both 100% for the 3D technique and 100% and 91%, respectively, for the 2D technique.

CONCLUSIONS: 3D-FSE T1WI accurately characterizes intraplaque components of the carotid artery, with excellent sensitivity and specificity compared with those of 2D-T1WI.

ABBREVIATIONS: CR = contrast ratio; SE = spin-echo

Cervical carotid stenosis is an important cause of cerebral infarction and transient ischemic attack. Carotid endarterectomy or carotid artery stent placement is performed to prevent future stroke events but may also cause embolic complications during the surgery, especially if the plaque contains substantial vulnerable components such as intraplaque hemorrhage or lipid.1,2 Therefore, establishing a method for characterizing intraplaque components is an important prerequisite for predicting perisurgical complications.

Several modalities have been used for plaque characterization, including ultrasonography and MR imaging. Although ultrasonography is widely used, the interpretation is typically subjective and may be impossible in the presence of extensive calcification or a high-positioned carotid bifurcation. Although gray-scale median and integrated backscatter have been introduced as quantitative metrics, previous reports suggest that they are unsuitable for evaluating intraplaque components.3,4 MR plaque imaging is another popular method for assessing plaque characteristics. Although various imaging techniques have been used, a 2D spin-echo (SE) T1WI technique with appropriate scanning parameters has been reported to accurately quantify intraplaque components, compared with other conventional techniques.5–8 Recently, a 3D T1WI FSE technique has been adopted for this purpose because it can minimize partial volume effects and motion artifacts, as well as enhance black-blood effects, while maintaining T1WI contrast. However, whether the 3D-FSE technique can more accurately discriminate among intraplaque components than the more conventional techniques, such as 2D-SE T1WI,
remains unknown. Hence, in the present study, we investigated whether the diagnostic accuracy of 3D-FSE T1WI, in terms of carotid plaque characterization, is comparable with that of 2D-SE T1WI, by using pathologic specimens excised from carotid endarterectomy as our validation standards.

MATERIALS AND METHODS

Patients
From July 2012 to December 2013, we prospectively examined 34 consecutive patients (age range, 58–79 years [mean, 70.4 years]; 31 men and 3 women) with substantial stenosis of the cervical internal carotid artery, all of whom underwent carotid endarterectomy. Of these patients, 26 had symptomatic stenosis of 50%–95%, according to the method of the North American Symptomatic Carotid Endarterectomy Trial, and 8 had asymptomatic stenosis of 70%–90%. The clinical profiles of the patients included hypertension (n = 28), hyperlipidemia (n = 27), and diabetes mellitus (n = 11). The institutional review board approved the study protocol, and written informed consent was obtained from all patients.

Imaging Protocol
Presurgery sagittal 3D-T1WI of the bilateral carotid bifurcation was performed by using a 1.5T MR imaging scanner (Signa HDxt; GE Healthcare, Milwaukee, Wisconsin) with an 8-channel neurovascular coil. The pulse sequence parameters were as follows: flow-sensitized 3D-FSE with variable flip angles; TR/TE, 500/18.3 ms; echo-train length, 24; b-value of the flow-sensitized gradients along 3 axes, 2.2 s/mm²; FOV, 25 cm; matrix size, 512 × 512 (after zero-fill interpolation); section interval, 0.5 mm (after zero-fill interpolation); partitions, 248; voxel size, 0.5 × 0.5 × 0.5 mm³; parallel imaging factor, 2; NEX, 1; fat suppression, chemical shift selective suppression; and acquisition time, 6 minutes 46 seconds. Nonselective saturation pulses were used as the black-blood technique.

Histologic Preparation
Specimens were excised en bloc from the affected carotid arteries and submitted for histologic evaluation. The specimens were fixed in formaldehyde, and transverse sections of the carotid bifurcations were carefully cut to correspond in direction and position to the 2D-MR images. During histologic preparation, hematoxylin-eosin, Masson trichrome, and anti-Glycophorin-A stains were applied to paraffin-embedded, 7-μm-thick sections. The sections of carotid plaque were classified into 6 types, according to the modified American Heart Association classification (Table 1).11

Data Processing and Statistical Analyses
After using the 3D-FSE images to generate reformatted axial images that corresponded to the 2D-SE images, we measured the signal intensity of the carotid plaque and the adjacent sternomastoid muscle by using the image with the largest plaque size. The images were randomized, and a blinded author (S.N.) manually traced the plaque and muscle 3 times, by using the polygon cursor of a free software package (zioTerm 2009; Ziosoft, Tokyo, Japan). The resulting signal intensity values were averaged, and the contrast ratio (CR) was calculated by dividing the average signal intensity of the plaque by that of the muscle.

Differences in the CRs of plaques among the various histologic types were examined by using the Kruskal-Wallis test, followed by the post hoc Mann-Whitney test. Differences between the 3D-FSE and 2D-SE techniques and those between the asymptomatic and symptomatic patients were examined by using the Wilcoxon signed rank test and the Mann-Whitney test, respectively. In addition, receiver operating characteristic curve analyses were performed to evaluate the sensitivity and specificity of the ability of the techniques to differentiate plaques containing substantial vulnerable components from those containing stable components. Vulnerable components were defined as lipid, necrosis, and/or hemorrhage (IV–V, VI), while stable components were defined as calcification and fibrous tissue (I–II, III, VII, VIII). Receiver operating characteristic curve analysis was also performed to evaluate the abilities of the techniques to differentiate hemorrhagic complex plaques (VI) from other plaques. Cutoff values were determined by using the Youden index, and differences in the areas under the receiver operating characteristic curves were examined by using the DeLong test. The intraoperator correlation coefficient was used to evaluate intraoperator agreements for the manual measurements. The α level used was .05.

RESULTS

Three patients were excluded because their carotid endarterectomy was postponed for >3 months after their MR imaging examinations. The remaining 31 patients were considered eligible for further quantitative analyses. Patient characteristics are as follows: age, ranging from 58 to 79 years (mean, 70.8 years); 28 men and 3 women; and interval between MR imaging and carotid endarterectomy, ranging from 1 to 82 days (median, 28 days). The number and type of carotid plaques, as determined by histopathologic examination, are shown in Table 1. Ischemic stroke events during the surgery occurred in the 2 symptomatic patients with carotid plaque type VI.

With 3D-FSE T1WI, the CR range and median values of the plaques that were histologically confirmed as types VII, VIII, IV–V, and VI were 0.94–0.97 (0.95), 0.95–1.29 (1.10), 1.33–1.54 (1.42), and 1.53–2.12 (1.80), respectively. The CR range and median value by using 2D-SE T1WI were 0.79–1.02 (0.90), 0.88–1.19 (1.01), 1.17–1.46 (1.23), and 1.55–2.51 (2.07), respectively. These values were significantly different among the groups, by using both the 3D-FSE and 2D-SE images. In addition, CRs of type IV–V plaques were significantly higher than those of types VII and VIII and are significantly higher on 3D-FSE images than on 2D-SE images. Sensitivity and specificity for discriminating between vulnerable plaques (IV–V and VI) and stable plaques (VII and VIII) were both 100%, by using the 3D-FSE images, and 100% and 91%, respectively, by using the 2D-SE images. Red circles indicate symptomatic patients; blue circles, asymptomatic patients; and arrows, patients showing ischemic events during surgery.

These values were significantly different among the groups, by using both the 3D-FSE and 2D-SE images (P < .001, Kruskal-Wallis test; Table 1 and Fig 1). Among the CRs of carotid plaques with various compositions, there were significant differences among all combinations of types VII, VIII, IV–V, and VI, which tended to show isointensity to the muscle, mild hyperintensity, and marked hyperintensity, respectively, on both the 3D-FSE and 2D-SE images (P < .01, post hoc Mann-Whitney test; Figs 1 and 2). The CRs of types IV–V plaques on the 3D images were significantly higher than those on the 2D images (P = .028, Wilcoxon signed rank test), while the CRs of the type VI plaques on the 3D images were significantly lower than those on the 2D images (P = .013, Wilcoxon signed rank test; Table 1). Furthermore, the CRs of the plaques in the symptomatic patients were significantly higher than those in the asymptomatic patients both on the 3D images (0.94–2.12 [median, 1.54] and 0.95–1.33 [median, 1.17], respectively; P = .004, Mann-Whitney test) and on the 2D images.

a Contrast ratios are presented as range (median).

b Kruskal-Wallis test.

c Wilcoxon signed rank test.
Electrolyte concentrations in the brain vary significantly among individuals. The intracellular concentrations are typically much higher than in the extracellular space. For example, Na⁺ is 100 times more concentrated inside the cell (150 mM) than outside (15 mM), while K⁺ is 10 times more concentrated outside (140 mM) than inside (140 mM). These concentration gradients are maintained by specific ion pumps and channels.

The brain is also exposed to a constant supply of nutrients and oxygen through the bloodstream. The capillary network provides a rich source of nutrients and oxygen, which are essential for neural function. The blood-brain barrier, a network of specialized endothelial cells, helps regulate the exchange of substances between the blood and the brain, allowing for the selective transport of molecules into the brain.

Another critical factor is the temperature regulation of the brain. The brain typically maintains a temperature of 37°C, which is slightly higher than the overall body temperature. This is maintained through a combination of blood flow regulation and metabolic processes. An increase or decrease in temperature can affect neural function and is closely monitored by the brain's temperature control mechanisms.

These factors, along with others such as pH and osmolarity, contribute to the complex environment within the brain, which is critical for the proper functioning of the nervous system.
sensitivity and specificity. In particular, the CRs of lipid-rich/necrotic plaques (types IV–V) on 3D-FSE images were significantly lower than those on 2D-SE images, resulting in less accuracy in differentiating hemorrhagic plaques from other plaques, presumably due to the inherent T2 dependency of the 3D-FSE technique caused by its prolonged effective TE. However, this result appears to hardly affect discrimination between unstable and stable plaques because the CRs of hemorrhagic plaques remained remarkably higher than those of stable plaques.

This study includes several limitations. First, although the 3D-FSE technique provides potential advantages in terms of partial volume effects, motion artifacts, and multidirectional capability, we did not directly compare these issues between the 2 techniques because our aim was to determine whether 3D-FSE had better contrast for use in plaque characterization than 2D-SE imaging. In general, 3D techniques are suitable for assessment of carotid plaques because the carotid artery is tortuous and pulsatile and the plaques are typically small, complex in shape and composition, and elongated in the superoinferior direction. Hence, 2D imaging is not ideal for visualizing carotid plaque characteristics in detail, given their limited section direction, thickness, and coverage, as well as their susceptibility to motion artifacts. 3D imaging, including 3D-FSE T1WI, might be able to overcome these limitations. Second, we examined CRs of the plaques by using only the section with the maximum plaque size. In this study, we had to abandon the idea of evaluating the whole plaque because only a single section was available for direct comparisons among the 3D images, 2D images, and corresponding histologic sections due to partial volume effects of the 2D images and difficulties in histologic preparation for the appropriate sections. Evaluation of the entire plaque may further improve the diagnostic performance, particularly for the 3D-FSE technique. Third, we could not simultaneously obtain the 3D-FSE and 2D-SE images by using the same scanner because these advanced sequences were implemented in distinct scanners. Hence, the images used for the comparisons may not have been obtained under identical conditions, which might have affected our results, though the intervals between the scans were 2–7 days in almost all patients. Fourth, we did not perform automated analyses that we reported previously,15 because appropriate cutoff values for differentiating plaque types on the 3D-FSE images were not known, though they were eventually elucidated in this study.

CONCLUSIONS

3D-FSE T1WI can accurately characterize carotid plaque composition mainly due to contrast improvement of the lipid-rich plaques and can differentiate vulnerable plaques from stable plaques with excellent sensitivity and specificity, being comparable with 2D-SE T1WI.
