Hemodynamic Differences in Intracranial Aneurysms before and after Rupture

ABSTRACT

BACKGROUND AND PURPOSE: Rupture risk of intracranial aneurysms may depend on hemodynamic characteristics. This has been assessed by comparing hemodynamic data of ruptured and unruptured aneurysms. However, aneurysm geometry may change before, during, or just after rupture; this difference causes potential changes in hemodynamics. We assessed changes in hemodynamics in a series of intracranial aneurysms, by using 3D imaging before and after rupture.

MATERIALS AND METHODS: For 9 aneurysms in 9 patients, we used MRA, CTA, and 3D rotational angiography before and after rupture to generate geometric models of the aneurysm and perianeurysmal vasculature. Intra-aneurysmal hemodynamics were simulated by using computational fluid dynamics. Two neuroradiologists qualitatively assessed flow complexity, flow stability, inflow concentration, and flow impingement in consensus, by using flow-velocity streamlines and wall shear stress distributions.

RESULTS: Hemodynamics changed in 6 of the 9 aneurysms. The median time between imaging before and after rupture was 678 days (range, 14–1461 days) in these 6 cases, compared with 151 days (range, 34–183 days) in the 3 cases with unaltered hemodynamics. Changes were observed for flow complexity \( n = 3 \), flow stability \( n = 3 \), inflow concentration \( n = 2 \), and region of flow impingement \( n = 3 \). These changes were in all instances associated with aneurysm displacement due to rupture-related hematomas, growth, or newly formed lobulations.

CONCLUSIONS: Hemodynamic characteristics of intracranial aneurysms can be altered by geometric changes before, during, or just after rupture. Associations of hemodynamic characteristics with aneurysm rupture obtained from case-control studies comparing ruptured with unruptured aneurysms should therefore be interpreted with caution.

ABBREVIATIONS: CFD = computational fluid dynamics; 3DRA = 3D rotational angiography; OSI = oscillatory shear index; WSS = wall shear stress

Intracranial aneurysms are found in 1%–5% of the adult population.\(^1,2\) For ruptured intracranial aneurysms, case morbidity and fatality rates are high.\(^1,3\) However, 50%–80% of all intracranial aneurysms do not rupture during an individual’s lifetime.\(^4\) More commonly, unruptured aneurysms are incidentally found due to increasing use of imaging.\(^4,5\) The risk of rupture should be balanced against the risk of treatment when deciding whether an aneurysm should be treated. In clinical practice, the location and size of the aneurysm are the most important parameters for determining the risk of rupture.\(^1,6\) However, these geometric predictors are insufficient for optimal treatment selection. Therefore, the search for better predictors for rupture continues.\(^7-9\) Previous studies have associated intra-aneurysmal flow patterns and wall shear stress (WSS) distributions with aneurysm rupture status.\(^7,8,10\) However, these results are still controversial. For example, both high and low aneurysmal WSS were separately associated with aneurysm growth and rupture.\(^11,12\) In these risk-assessment studies, potential changes in hemodynamics due to the rupture itself were systematically neglected. Recently, 2 studies have shown changes in aneurysm geometry after rupture.\(^13,14\) These rupture-associated geometric changes may result in differences in hemodynamic characteristics as well.

In this study, we had the opportunity to use high-quality 3D imaging data of 9 patients with intracranial aneurysms, obtained before and after rupture, to assess potential differences in hemodynamic characteristics associated with rupture.

**MATERIALS AND METHODS**

3D image data of intracranial aneurysms for 9 patients before (MRA [n = 6], CTA [n = 3]) and after (CTA [n = 2], 3D rotational angiography [3DRA, n = 7]) rupture were collected. The imaging parameters are shown in Table 1.14 Clinical data and aneurysmal geometric data are shown in the On-line Table. The image data were collected during 6 years in 3 different institutions. Four male and 5 female patients were included, with aneurysms located at the basilar artery (n = 3), posterior communicating artery (n = 2), middle cerebral artery (n = 2), anterior communicating artery (n = 1), and anterior choroidal artery (n = 1). The mean age at the time of rupture was 60 ± 12 years. The median time between imaging before and after rupture was 183 days, with a range of 14 days to 4 years 1 day. The median time between rupture and subsequent imaging was 1 day, with a range of 0–9 days. Informed consent was waived by the medical ethics committee because no diagnostic tests other than routine clinical imaging were used in this retrospective study.

**Vascular Model Generation**

To create a surface model of the aneurysm and perianeurysmal vasculature by using the available 3D imaging data, we used a level set algorithm of the Vascular Modeling Toolkit (http://www.vmtk.org/).15-18 For hemodynamic simulation, model accuracy and mesh quality are important.18,20 Therefore, inaccuracies due to imaging artifacts such as flow dispersion and saturation in 3D time-of-flight MRA, partial voluming, beam hardening (in CTA), neck size overestimation,22 and inhomogeneous contrast agent distribution (in CTA and 3DRA) were corrected. Artificial narrowing results in overestimations of WSS and erroneous flow velocities22 and was, therefore, corrected by inflation by using Blender (http://www.blender.org).23 Vessel inflation was performed in the proximal arteries in 13 models and in the distal arteries in 12 models. Furthermore, the inflow jet and location of deflection may be sensitive to the segmentation of the neck area. To reduce this dependency, an experienced neuroradiologist (C.B.L.M.M.) carefully inspected the vascular models and corrected them for imaging artifacts. Imaging artifacts were distinguished from pathology by using additional DSA imaging. For the purpose of this study, manual corrections of the segmentation were performed by using ITK-SNAP 2.4.0 (www.itksnap.org).24 In addition, the surface models were smoothed by using a built-in Taubin-smoothing algorithm of the Vascular Modeling Toolkit to remove high-frequency noise while preventing the surface models from shrinking.25

Subsequently, all aneurysm models were inspected for apparent differences in visualized anatomy of perianeurysmal arteries before and after rupture. The vascular models agreed for all except 1 case. In case 8, we removed 2 outflow arteries from the ruptured model because in the before-rupture imaging, only 1 outflow artery was visible, while 3 outflow arteries were visible in the after-rupture imaging.

To decrease computational effort, we removed distant vessel branches located approximately 20 times the average radius distal to the aneurysm. Finally, the in- and outlet vessels were cut perpendicular to the vessel. To ensure fully developed flow entering the aneurysm model, we added cylindrical flow extensions, with a length of 12 times the radius of the afferent vessel, to the inlets of the models.18,26

All surface models were converted into tetrahedral meshes by using the Vascular Modeling Toolkit.18 The element attenuation close to the wall was increased by adding a customized boundary layer. The median number of elements was 3,284,000 (range 2,101,000–5,248,000).

**Computational Fluid Dynamics**

Computational fluid dynamics (CFD) (Fluent 13.0; ANSYS, Canonsburg, Pennsylvania) was used to simulate hemodynamics in the vascular models. Transient Navier-Stokes equations were solved by using a pressure-based, 3D double-precision solver by following the SIMPLE Method.27 Blood was modeled with an attenuation of 1060 kg/m3 and a dynamic viscosity of 0.004 Pa·s. A no-slip boundary was assumed at the rigid vessel wall.

Because patient-specific velocity data were not available for this patient selection, we calculated parent artery–specific velocity profiles for the basilar artery (cases 1, 6, and 9), internal carotid artery (cases 3, 7, and 8), middle cerebral artery (cases 4 and 5), and anterior cerebral artery (case 2). Median values for the maximum and minimum velocities were obtained from previous patient-specific 4D phase-contrast MR imaging velocity measure-
The altered hemodynamics are the consequence of a change in morphology and hemodynamics. However, our study shows that hemodynamic characteristics changed in 6 of the 9 aneurysms in the period between image acquisitions. Notably, we show changes in flow complexity, stability, and concentration, which have been associated with a risk of rupture.

Qualitative Characterization: Case-by-Case Description

For cases 1 and 6, aneurysmal geometry and hemodynamics did not change after rupture. In case 2, the aneurysm was displaced 8.9 mm after rupture, most likely due to mass effect from a large perianeurysmal hematoma (dimensions, 28 × 22 × 35 mm). In this case, the region of flow impingement changed from the dome to the body. In the On-line Video, changes of WSS distributions before (A) and after (C) rupture with velocity magnitude streamlines before (B) and after (D) rupture of this case can be appreciated.

Case 3 showed a relative growth of 79% with 1 new lobulation after rupture. The flow profile changed from simple and stable to complex and unstable after rupture.

The aneurysm of case 4 was displaced 5.8 mm after rupture, most likely due to mass effect from a large perianeurysmal hematoma (dimensions, 46 × 33 × 38 mm). However, there were no changes in hemodynamic characterizations.

In case 5, a volumetric increase of 176% and a displacement of 1.2 mm after rupture were found. For the hemodynamic characterization, a diffuse inflow pattern before rupture changed to a concentrated one after rupture.

In case 7, there was a relative growth of 70% and a displacement of 2.5 mm after rupture. The flow pattern changed from stable to unstable. Before rupture, the inflow stream impacted the aneurysm at 2 regions: the aneurysm neck and body. After rupture, the neck of the aneurysm was the only region of impingement.

In case 9, a new lobulation was observed in the imaging after rupture. The flow changed from simple and stable to complex and unstable.

RESULTS

Streamlines at peak systole and heart cycle–averaged WSS distributions of all 18 vascular models are shown in Figs 2 and 3, respectively. All vascular models had a single inflow jet, single or multiple vortices, and at least 1 clear impingement zone before and after rupture. The location of maximum WSS and the region of flow impingement agreed for all cases. Hemodynamic differences were observed in 6 of the 9 aneurysms (Table 2). For the 6 patients with hemodynamic changes, the median time between imaging before and after rupture was 678 days (range, 14–1461 days). For the 3 patients without hemodynamic changes, this was 151 days (range, 34–183 days). Flow complexity changed from simple to complex in 3 cases. Flow stability changed from stable to unstable in 3 cases. The inflow concentration changed from diffuse to concentrated in 1 case and from concentrated to diffuse in another case. The region of flow impingement changed in 3 cases. These hemodynamic changes were associated with growth, aneurysm displacement, or newly formed lobulations.

Changes in OSI after rupture ranged from −0.037 to +0.034 and from −0.030 to +0.12 for the spatially averaged and maximum values, respectively (Table 3).

Qualitative Analysis
Flow-velocity magnitude streamlines and WSS distributions were visualized by using Paraview 3.6.2 (Kitware; Los Alamos National Laboratory, Los Alamos, New Mexico). The visualizations were qualitatively assessed by 2 experienced neuroradiologists (C.B.L.M.M., R.v.d.B.) for hemodynamic characteristics in consensus. Flow complexity, flow stability, and the inflow concentration were assessed on the basis of visualization of the streamlines. The region and size of flow impingement were determined from the WSS distribution and streamlines.

Quantitative Oscillatory Shear Index Measurements
The mean and maximum oscillatory shear indices (OSIs) were calculated to assess the directional change of WSS during the cardiac cycle. Differences in OSI values before and after rupture were determined.

DISCUSSION

Most current rupture-risk identification studies compare models of ruptured aneurysms with unruptured models and ignore the possibility that the rupture itself may change aneurysm morphology and hemodynamics. However, our study shows that hemodynamic characteristics changed in 6 of the 9 aneurysms in the period between before and after imaging. Notably, we show changes in flow complexity, stability, and concentration, which have been associated with a risk of rupture.

The altered hemodynamics are the consequence of a change in morphology in the period between image acquisitions. Because of the large imaging time interval in some cases, we cannot relate the
observed hemodynamic alterations to sudden, rupture-related morphologic changes alone. For instance, growth or lobulation formation may also have occurred more gradually during the whole time span. This scenario agrees with the median time between before and after rupture imaging, which was much larger for the cases with hemodynamic changes than for the cases without. Furthermore, all of the 3 cases in which flow patterns changed from simple to complex showed a newly formed lobulation. How-

FIG 2. Flow-velocity streamlines (m/s) for all 9 aneurysms before and after rupture. For each aneurysm, the time-step with the peak velocity–magnitude of the inflow artery is shown.

FIG 3. Heart cycle–averaged WSS (Pascal) distributions for all 9 aneurysms before and after rupture.
ever, morphologic changes may also occur suddenly, shortly be-
fore, during, or just after rupture. This change can be illustrated
by the large growth of case 8 within 14 days and by the aneurysm
displacement in both cases (2 and 4) with a hematoma with mass
effect.

Therefore, hemodynamics of ruptured models may still be
valuable for gradually changing aneurysms, where the value seems
more limited for models with rupture-related morphologic
changes. In most cases, it is difficult to discriminate between sud-
den and gradual changes in morphology, except for cases with
large perianeurysmal hematomas. We recommend excluding
these cases in studies that compare hemodynamic characteristics
in ruptured and unruptured aneurysms because hematomas may
strongly influence hemodynamics.

Only a few studies assessed hemodynamics both before and
after rupture. In 4 aneurysms of the posterior communicating
artery, Chien and Sayre determined that only 1 hemodynamic
parameter (pulsatility index) was not affected by rupture. This
agrees with our observations that most hemodynamic character-
istics changed. Duan et al examined hemodynamic and mor-
phologic parameters by using a case-control study of 6 aneurysms
on the posterior communicating artery with hemodynamic data
within 7 days before rupture. However, they only compared pa-
rameters with those of matched controls and did not investigate
the influence of the rupture itself. This was also the case in the
study of Liu et al, in which low WSS was associated with rupture
in a case-control study of large internal carotid artery aneurysms,
including 3 unruptured aneurysms just before rupture and 8 un-
ruptured controls. A recent case report of an aneurysm with im-
aging before and just after rupture demonstrated changes in WSS
values between 20% and 30%, caused by a change in the aneurysm
shape. 34

In a recent study by Bor et al,35 aneurysm growth was studied
in a large population of patients with unruptured and untreated
intracranial aneurysms. In their study, >10% of the aneurysms
grew during a mean follow-up time of <3 years. Growth is con-
sidered a marker for increased risk of rupture, and because growth
may change hemodynamics, such a population allows improved
characterization of hemodynamic rupture-risk factors.

A previous study by Xiang et al showed that high OSI values
were associated with ruptured aneurysms. We indeed found high
OSI values in all ruptured models. Most important, OSI was also
high in all except 1 of the unruptured models. The exception was
a case with >3 years between imaging, in which gradual progres-
sion from low-to-high shear stress oscillation might have been
missed. These data therefore suggest that high OSI values may
remain valuable for risk prediction.

**Limitations**
The current study has a number of limitations. Although this
study is the largest comparing hemodynamic parameters within
aneurysms before and after rupture, the number of patients was
too small to perform statistical analysis. CFD is sensitive to the
geometry and therefore image resolution, and neck size overesti-
mation can affect the calculated hemodynamic parameters.13 Pre-
vious literature concluded that WSS calculations are strongly de-

- OSI values range from 0 to 1, with higher values indicating greater oscillatory shear stress.
- The mean OSI and maximum OSI values are presented with standard deviations.

---

pended on segmentation and resolution. Because of the large variation in resolution, the WSS estimations were not robust. Therefore, we used WSS distributions only for determining the impingement region, and no absolute WSS values were reported. Manual corrections for imaging artifacts were performed by a single neuroradiologist. These imaging artifacts were apparent in all cases; therefore, we do not expect large variations among different observers. Furthermore, common limitations for CFD studies, such as the generic pulsatile waveform, rigid wall assumption, limited accuracy of the algorithm, Newtonian fluid assumption, and CFD solution strategies may affect the accuracy of CFD results.

**CONCLUSIONS**

We have shown that morphologic changes before, during, or just after rupture may result in differences in hemodynamic characteristics between the ruptured and unruptured status of aneurysms. Hemodynamic differences were associated with aneurysm growth, lobulation formation, and displacement due to hematoma. Associations of hemodynamic characteristics with aneurysm rupture obtained from case-control studies comparing ruptured and unruptured aneurysms should, therefore, be interpreted with caution and not automatically used in risk models for aneurysm rupture.
