ABSTRACT

BACKGROUND AND PURPOSE: Rupture of the plaque fibrous cap and subsequent thrombosis are the major causes of stroke. This study evaluated morphologic features of plaque rupture in the carotid artery by using optical coherence tomography in vivo.

MATERIALS AND METHODS: Thirty-six carotid plaques with high-grade stenosis were prospectively imaged by optical coherence tomography. “Plaque rupture” was defined as a plaque containing a cavity that had overlying residual fibrous caps. The fibrous cap thickness was measured at its thinnest part for both ruptured and nonruptured plaques. The distance between the minimum fibrous cap thickness site and the bifurcation point was also measured. Optical coherence tomography identified 24 ruptured and 12 nonruptured plaques.

RESULTS: Multiple ruptures were observed in 9 (38%) patients: Six patients had 2 ruptures in the same plaque, 2 patients had 3 ruptures in the same plaque, and 1 patient had 5 ruptures in the same plaque. Most (84%) of the fibrous cap disruptions were identified at the plaque shoulder and near the bifurcation point (within a 4.2-mm distance). The median thinnest cap thickness was 80 μm (interquartile range, 70–100 μm), and 95% of ruptured plaques had fibrous caps of <130 μm. Receiver operating characteristic analysis revealed that a fibrous cap thickness of <130 μm was the critical threshold value for plaque rupture in the carotid artery.

CONCLUSIONS: Plaque rupture was common in high-grade stenosis and was located at the shoulder of the carotid plaque close to the bifurcation. A cap thickness of <130 μm was the threshold for plaque rupture in the carotid artery.

ABBREVIATION: OCT = optical coherence tomography

fibrous cap that could not be measured by other imaging modalities.\textsuperscript{13} In the present study, we evaluated the morphologic features of ruptured plaques in the carotid artery by using OCT.

**MATERIALS AND METHODS**

**Study Population**

Between March 2012 and November 2013, a prospective but non-consecutive series of 38 carotid arteries in 36 patients who were scheduled for carotid artery stenting to treat a high-grade stenosis in previously untreated carotid arteries underwent diagnostic OCT examinations to evaluate plaque morphology. OCT was performed only when carotid artery stenting was planned under proximal protection methods, due to the need for continuous injection of saline and contrast through the guiding catheter to remove blood from the FOV. Patients with a moderate stenosis at the proximal common carotid artery, a very tight stenosis at the target lesion, and intramural thrombus suspected on the basis of other modalities were not enrolled in this study because of the potential difficulty in acquiring and interpreting OCT images with such conditions. OCT examinations were performed for 38 carotid arteries in 36 patients, with 2 patients undergoing bilateral carotid artery stenting. Two patients were excluded because of poor OCT images. Finally, 36 carotid arteries in 34 patients were considered eligible for performing OCT image assessments. The grade of carotid stenosis was assessed by using angiography,\textsuperscript{13} and indications for carotid artery stenting were based on the Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy trial.\textsuperscript{14} Because OCT is approved only for coronary arteries, its use in human carotid arteries was approved by our institutional ethics committee (No. 21–108), and the study protocol was submitted to an open-access data base (University Hospital Medical Information Network, trial number UMIN 00002808; http://www.umin.ac.jp/english/). Informed consent was obtained from all patients before participation.

**OCT Procedure**

Frequency domain OCT imaging was performed by using a C7-4R OCT imaging system (St. Jude Medical, St. Paul, Minnesota). A 9F guiding catheter with an occlusion balloon was inserted into the common carotid artery, and a guidewire with an occlusion balloon (GuardWire; Medtronic, Minneapolis, Minnesota) was introduced into the external carotid artery; or a 9F Mo.Ma system (Medtronic), which has 2 compliant balloons, was inserted where the distal balloon was located in the external carotid artery and the proximal balloon was located in the common carotid artery. Following a Z offset adjustment, an OCT imaging catheter (Dragonfly; St. Jude Medical) was advanced into the carotid artery beyond the stenotic site over a 0.014-inch microguidewire. After the OCT catheter placement, a carefully debubbled mixture of saline and contrast (1:1 dilution) (iomeprol, Iomeron 300; Bracco, Milan, Italy) at 37°C was flushed through the guiding catheter at a rate of 6 mL/s for a 5-second period by using a motor-driven injector. When a blood-free image was observed, the OCT imaging core was withdrawn by using a stand-alone electronic control of the pullback motor. We stored OCT images digitally for subsequent analysis.

**OCT Imaging Analysis**

All images were recorded digitally and analyzed by 2 independent investigators who were blinded to the clinical presentations and angiographic findings. Qualitative OCT assessment was performed for each artery by using previously published criteria.\textsuperscript{15} Plaques were classified as the following: 1) fibrous (homogeneous with high backscatter regions), 2) lipid-rich (low-signal region with diffuse border), or 3) calcified (low backscattering signal with a sharp border inside a plaque). For all nonruptured plaques that were determined lipid-rich with OCT, the fibrous cap thickness was measured at its thinnest part. The cap thicknesses were measured 3 times, and the average value was calculated. The distance between the minimum fibrous cap thickness site and the carotid bifurcation point was measured. “Plaque rupture” was defined as a plaque containing a cavity that was in contact with the lumen that had any overlying residual fibrous cap fragment.\textsuperscript{16} Rupture sites separated by a length of artery containing smooth lumen contours and no cavity were considered to represent different plaque ruptures. The thinnest cap thickness was measured at the thinnest part of the remnant of the disrupted fibrous cap. The distance between the plaque rupture site and the carotid bifurcation point was also measured. The largest intraplaque cavity was measured and extrapolated to the ruptured capsule area. Representative measurements of the thinnest part of ruptured and nonruptured caps are shown in Fig 1. “Thrombus” was defined as a backscattering protrusion into the carotid lumen with signal-intensity-free shadowing.\textsuperscript{17} “Neovascularization” was defined as a microchannel structure with no signal intensity without a connection to the vessel lumen that was present in ≥3 continuous cross-sections of the OCT images.\textsuperscript{18}

Identification of 2 separate plaques in the same artery (ie, infarct-related versus non–infarct-related lesion) required a 5-mm reference segment between them; if not, they were considered to be part of 1 long lesion.

**Statistical Analysis**

JMP, Version 10.0 (SAS Institute, Cary, North Carolina) was used for all statistical analyses. Categoric data were expressed as absolute frequencies and percentages and were compared by using the χ² or Fisher exact test, as appropriate. Continuous variables were expressed as either mean ± SD for normally distributed variables or median (interquartile range, 25th to 75th percentiles) for non-normally distributed variables and were compared by using either an unpaired Student t test or a Mann-Whitney U test, respectively. Receiver operating characteristic analysis was used to determine the best cutoff cap thickness values for discriminating ruptured and nonruptured plaques. The κ statistic was used to define the level of intra- and interobserver agreement in the identification of plaque rupture. The interobserver variability for measuring the fibrous cap thickness was assessed by linear regression analysis. P < .05 was regarded as a statistically significant difference.

**RESULTS**

The average time required for the OCT examination was 5.6 ± 1.3 minutes. No technical or neurologic complications were encountered during OCT procedures, though transient carotid artery occlusion and continuous infusion of saline and contrast media were nec-
esary during the time required for imaging. The average pullback length imaged by OCT was 54 mm. Among all of the 36 arteries examined, OCT identified 24 ruptured (67%) and 12 nonruptured (33%) plaques.

**Patient Characteristics**

Patient characteristics and angiographic findings are presented in Table 1. There were no statistically significant differences in terms of age, sex, or other important stroke risk factors between patients with plaque rupture and those without plaque rupture.

**Fibrous Cap Thicknesses between Ruptured and Nonruptured Plaques**

Thirty-eight plaque ruptures in 24 arteries were identified by OCT. Of the 24 arteries with plaque ruptures, multiple ruptures were observed in 9 arteries (38%): Six patients had 2 OCT ruptures in the same artery, 2 patients had 3 ruptures each in the same artery, and 1 patient had 5 ruptures in the same artery. In the remaining 12 arteries without plaque ruptures, OCT identified 12 nonruptured lipid-rich plaques in which the fibrous cap thickness could be reliably measured. OCT findings are summarized in Table 2. Among the findings presented, neovascularization was frequently identified in ruptured plaques compared with nonruptured plaques (54% versus 17%, \( P < .03 \)). The median cap thickness at the thinnest part of the cap was significantly thinner in ruptured fibrous caps than in nonruptured fibrous caps (80 \( \mu \)m [interquartile range, 70–100 \( \mu \)m] versus 175 \( \mu \)m [155–238 \( \mu \)m]; \( P < .001 \)). The fibrous cap thickness was thinner than 130 \( \mu \)m in 95% of ruptured plaques and thicker than 130 \( \mu \)m in 85% of nonruptured plaques. Figure 2 shows the frequency distribution of ruptured and nonruptured plaques according to the cap thickness measured at the thinnest part. On the basis of the receiver operating characteristic analysis, the optimal cap thickness for predicting plaque rupture was <130 \( \mu \)m (Fig 3).

The \( \kappa \) statistic for intraobserver and interobserver variability for plaque rupture imaging was 1.00 and 1.00, respec-
The measurement of fibrous cap thickness by OCT showed excellent interobserver reproducibility ($r = 0.73, P < .01$). Spatial Distribution and the Largest Ulcer Areas of Ruptured Plaques

Eight ruptured sites (21%) were located in the common carotid artery, and 30 (79%), in the internal carotid artery. The median area of the ruptured plaque cavity measured 1.38 mm$^2$ (interquartile range, 0.35–3.03 mm$^2$). In all plaque ruptures, the site of the original tear in the fibrous cap could be identified; 26% (10/38) of tears appeared to have occurred in the center of the plaque, and the rest (74%), at the shoulder of the plaque. The image section with plaque rupture was located at the narrowest lumen site in only 6 (16%) plaques. A representative case that has plaque ruptures at the shoulder of the plaque is shown in Fig 4. The rupture site was proximal to the narrowest lumen site in 22 plaques (58%), and distal to the narrowest lumen site in 10 plaques (26%). In all plaques, the image section with the narrowest lumen area was near the bifurcation point. The median distance between the narrowest lumen site and the bifurcation point measured 4.2 mm (interquartile range, 2.2–13.8 mm) in ruptured plaques and 6.7 mm (interquartile range, 3.0–8.8 mm) in nonruptured plaques ($P = .67$). Similarly, the median distance between the fibrous cap thickness at the thinnest part and the bifurcation point was 4.6 mm (interquartile range, 0–12.0 mm) in ruptured plaques and 5.0 mm (interquartile range, 1.3–10.5 mm) in nonruptured plaques ($P = .82$).

DISCUSSION

The main findings of the present study were the following: Plaque ruptures were frequently observed within carotid arteries with a high-grade stenosis; plaque ruptures may be multiple; fibrous cap thickness of $<130 \mu m$ was the critical threshold for plaque rupture in the carotid artery; and most of the rupture tears were located at the shoulder of the carotid plaque but close to a side branch.

Fibrous Cap Thicknesses between Ruptured and Nonruptured Plaques

Carotid plaque composition has been proposed as an important risk factor for thromboembolic events, such as stroke, giving rise to the concept of “vulnerable plaque.” It has been suggested that thromboembolic phenomena are associated with thinning and subsequent rupture of the fibrous cap on the surface of atherosclerotic plaques, resulting in the release into the parent vessel of necrotic debris from the plaque substance. Several studies have established a correlation between plaque rupture and irregularity with clinical presentation and prognosis. Therefore, the identification of the fibrous cap is especially important because its thickness is a major determinant of plaque vulnerability in a lipid-rich carotid plaque. OCT is the only imaging technique that can resolve intracoronary features on the scale of the thickness of a rupture-prone cap. Kume et al$^{12}$ reported that OCT provides an accurate rep-
presentation of the thickness of the fibrous cap that could not be measured by other imaging modalities.

Virmani et al defined plaque vulnerability on the basis of the actual thickness of the histologic section from measurements made of coronary plaque ruptures. A thickness of 65 μm was considered a criterion of plaque instability in the coronary arteries because the average cap thickness was 23 ± 19 μm in ruptured plaques and 95% of the disrupted caps were <65-μm-thick. Thus, the fibrous cap thickness of <65 μm has been widely used as the definition of in vivo coronary vulnerable plaque that is prone to rupture. Recently, Yonetsu et al evaluated the critical threshold of fibrous cap thickness for coronary plaque rupture by using OCT. They reported that the fibrous cap thickness was <80 μm in 95% of ruptured coronary plaques and the median fibrous cap thickness of ruptured plaques was 54 μm. Although the values of the critical threshold for the disruption of the fibrous cap in coronary plaques are similar regardless of the methodology, there are large discrepancies in the values of the critical threshold for carotid plaques. The critical cap thickness of carotid plaques might be thicker than that of coronary plaques because the hemodynamic forces acting at the carotid bifurcation are greater in the carotid artery.

Redgrave et al conducted a histologic evaluation of 526 carotid plaques from patients undergoing endarterectomy for symptomatic severe stenosis. They reported that the median cap thickness was 150 μm in ruptured plaques, and the optimum cutoff for discriminating ruptured and nonruptured plaques was a minimum cap thickness of <200 μm. On the contrary, a previous in vivo study by using sonography found that the critical cap thickness in carotid plaques was 460 μm. In the current OCT study, the median thickness of a fibrous cap at the thinnest part was 80 μm and 95% of ruptured plaques had a fibrous cap thickness that was thinner than 130 μm. Possible reasons for the large discrepancy between the current OCT study and the previous sonography and postmortem studies are not entirely clear; however, possible points of difference may include study population variations and a small sample size of ruptured plaques in these studies. However, detection of plaques with complex morphology, such as a thin-cap fibroatheroma, may be more precise with OCT than with sonography because the higher resolution of OCT permits accurate measurement of the thin fibrous cap.

**Spatial Distribution of Ruptured Plaques**

From postmortem studies, it is known that fibrous caps vary widely in thickness, cellularity, matrix, strength, and stiffness, but they are often thinnest (and macrophage infiltration is greatest) at their shoulder regions where disruption most frequently occurs. The current study revealed that plaque ruptures were distinct

---

**FIG 3.** Receiver operating characteristic curves for measurements of fibrous cap thickness for the prediction of fibrous cap rupture. The optimal cap thickness value for predicting rupture was a cap thickness of <130 μm (area under the curve, 0.95; sensitivity, 94.7%; and specificity, 93.3%).

**FIG 4.** A representative patient (64-year-old man) with a 90% stenosis in the right internal carotid artery. A high-grade stenosis in the internal carotid artery was identified on the angiogram (A). The disruptions of the plaques (asterisks) were identified near the bifurcation, but not at the narrowest lumen site (double dagger) in the optical coherence tomography longitudinal view (B and C). A ruptured plaque contains a cavity that communicates with the lumen with an overlying residual fibrous cap fragment (D and E).
from minimum lumen sites in 74%. These data confirm previous reports showing that plaque rupture occurs most often at the shoulder of the plaque.27 A previous histopathologic study demonstrated that inflammation of the atherosclerotic cap and shoulder of the plaque was a common and locally observed phenomenon in coronary arteries, similar to our findings.26 Activated metalloproteinases may be expressed more commonly at the shoulder of the vulnerable plaque.27–29 In the current study, 58% of ruptured plaques were located in the proximal shoulder of the site with the most stenosis; the distance between the location of the minimum cap thickness and the bifurcation point measured 4.6 mm for ruptured plaques and 5.0 mm for nonruptured plaques. Severe stenoses produce flow turbulence that may increase stress on the nearby segment. In addition, endothelial cells near branches of a vessel have a reduced ability to repair wounds compared with cells from nonbifurcation regions.30

**Study Limitations**

Several limitations of the present study should be considered. First, this study was a single-center study with a relatively small study population. Further multicenter studies are required to reconfirm the results in a larger number of patients. Second, because the proximal segments of the target carotid arteries had to be occluded to remove blood from the imaging field during OCT image acquisition, some patients were not enrolled in this study if there was a potential difficulty in performing the proximal segment occlusion. Third, we also excluded patients who received emergent carotid artery stent placement because such patients must be treated as soon as possible. This selection bias might affect the results. Fourth, the penetration depth of OCT imaging is limited almost entirely by basic tissue optical properties and is the chief limitation of the technique, providing between 0.5 and 1.5 mm of imaging depth in most tissue types. Therefore, some ruptured plaques might be missed, especially when the cavity was filled by a lipidic component. Fifth, qualitative assessment of plaque composition by OCT may limit its diagnostic accuracy. However, this study confirmed that OCT demonstrated excellent reproducibility for the identification of plaque rupture. Finally, there are no data showing that OCT provides an accurate representation of the thickness of the fibrous cap in carotid plaques.

**CONCLUSIONS**

OCT showed that plaque rupture was common in carotid arteries with high-grade stenosis and was located at the shoulder of the carotid plaque close to a side branch. A fibrous cap thickness of <130 μm was the critical threshold for plaque rupture in the carotid artery. Future prospective large-scale in vivo studies are required to validate whether the fibrous cap thickness of <130 μm predicts plaque rupture and subsequent thromboembolic events for patients with carotid artery disease.
