

Even Small Decreases in Blood Pressure during Conscious Sedation Affect Clinical Outcome after Stroke Thrombectomy: An Analysis of Hemodynamic Thresholds

M.K. Whalin, K.M. Halenda, D.C. Haussen, L.C. Rebello, M.R. Frankel, R.Y. Gershon, and R.G. Nogueira

ABSTRACT

BACKGROUND AND PURPOSE: The adverse effects of general anesthesia in stroke thrombectomy have been attributed to intraprocedural hypotension, yet optimal hemodynamic targets remain elusive. Identifying hemodynamic thresholds from patients without exposure to general anesthesia may help separate the effect of hypotension from the effect of anesthesia in thrombectomy outcomes. Therefore, we investigated which hemodynamic parameters and targets best correlate with outcome in patients treated under sedation with monitored anesthesia care.

MATERIALS AND METHODS: We performed a retrospective analysis of a prospectively collected data base of patients with anterior circulation stroke who were successfully reperfused (modified TIC1 \geq 2b) under monitored anesthesia care sedation from 2010 to 2015. Receiver operating characteristic curves were generated for the lowest mean arterial pressure before reperfusion, both as absolute values and relative changes from baseline. Cutoffs were tested in binary logistic regression models of poor outcome (90-day mRS $>$ 2).

RESULTS: Two-hundred fifty-six of 714 patients met the inclusion criteria. In a multivariable model, a \geq 10% mean arterial pressure decrease from baseline had an OR for poor outcome of 4.38 (95% CI, 1.53–12.56; $P <$.01). Other models revealed that any mean pressure of $<$ 85 mm Hg before reperfusion had an OR for poor outcome of 2.22 (95% CI, 1.09–4.55; $P =$.03) and that every 10-mm Hg drop in mean arterial pressure below 100 mm Hg had an OR of 1.28 (95% CI, 1.01–1.62; $P =$.04).

CONCLUSIONS: A \geq 10% mean arterial pressure drop from baseline is a strong risk factor for poor outcome in a homogeneous population of patients with stroke undergoing thrombectomy under sedation. This threshold could guide hemodynamic management of patients during sedation and general anesthesia.

ABBREVIATIONS: MAC = monitored anesthesia care; MAP = mean arterial pressure

Retrospective studies have found that performing thrombectomies with the patient under general anesthesia may be associated with worse outcomes,^{1,2} possibly because of the increased incidence and severity of hypotension compared with the use of conscious sedation.³ Hypotension before reperfusion may compromise collateral blood flow and negatively impact outcomes in acute ischemic stroke. Previous investigations demonstrated that a lowest recorded systolic blood pressure of $>$ 140 mm Hg during endovascular therapy for acute ischemic stroke is associated with good neurologic outcome.³ Our group subsequently showed that a lowest mean arterial pressure (MAP) of \geq 70 mm Hg is an independent predictor of favorable neurologic outcome.⁴

These studies were limited because they included a mix of patients receiving conscious sedation and general anesthesia. In this setting, the association between general anesthesia and hypotension may make it difficult to discern the independent effects of blood pressure regardless of anesthesia type. We hypothesized that hypotension influences outcome even in those patients not exposed to general anesthesia. Our aim was to determine optimal hemodynamic parameters and thresholds for patients with acute stroke undergoing thrombectomy under conscious sedation with monitored anesthesia care (MAC). Such parameters could be used in future studies of outcome and anesthesia type to determine whether general anesthesia has deleterious effects independent of hypotension.

MATERIALS AND METHODS

After approval from the institutional review board, we retrospectively reviewed the records of 714 patients who underwent endovascular treatment for acute ischemic stroke in the neurointerventional suite of Grady Memorial Hospital from September 2010 to April 2015. Five hundred ninety-nine patients had anterior circulation stroke with 90-day outcome data. We had complete

hemodynamic data for 309 of the 347 patients treated under MAC. Two-hundred seventy-six of these patients were successfully reperfused (as defined by modified Thrombolysis in Cerebral Infarction 2b/3),⁵ with a median procedure time of 64 minutes (interquartile range, 43–96 minutes). We excluded 20 patients (7%) who were not reperfused within 2.5 hours of groin puncture, which left a study population of 256. The baseline characteristics and periprocedural variables of our study population were collected prospectively within the study period (September 2010 to April 2015) from the Marcus Stroke and Neuroscience Center endovascular data base. Good outcome was defined as a 90-day modified Rankin Scale score of 0–2.

Stroke Variables and Procedures

Patients were selected for thrombectomy on the basis of the presence of salvageable tissue on imaging. TICI scores were determined in the angiography suite by the operator. Three-fourths of the procedures were performed with stent retrievers, and the remainder used thromboaspiration. All patients had follow-up imaging to assess hemorrhage. The modified Rankin Scale scores at 90 days were determined by an in-person follow-up appointment. Occasional no-shows were estimated by a structured phone interview.⁶

Anesthesia Variables

Our anesthesia care team includes an attending anesthesiologist supervising a nurse anesthetist or anesthesiologist assistant. More than 95% of our MAC procedures use dexmedetomidine infusions with supplemental fentanyl and midazolam as needed. For most patients with MAC, blood pressure measurements are non-invasive and arterial lines are usually reserved for patients with severe cardiac disease. Infusion regimens vary by practitioner but usually involve a loading dose of 0.5–1 $\mu\text{g}/\text{kg}$ delivered during 10 minutes followed by a maintenance infusion of 0.5–1 $\mu\text{g}/\text{kg}/\text{hour}$. Although we did not have a formal protocol for hemodynamic management during this time, the target range for systolic blood pressure was usually set between 140 and 180 mm Hg before reperfusion. Phenylephrine was the most commonly used vasopressor. Anesthetic variables, including type of sedation, use of vasopressors, and systolic and diastolic blood pressure values (charted every 5 minutes), were retrieved from the anesthesia records. The baseline systolic and diastolic pressures were determined by averaging the measurements before the start of sedation. The single lowest MAP before successful reperfusion was recorded with its component systolic and diastolic blood pressures. We focused on MAP variables because mean blood pressure is directly measured by the noninvasive cuffs used on most patients, whereas these cuffs use an algorithm to derive systolic and diastolic blood pressure.⁷

Statistical Analysis

All data are expressed as mean \pm SD or median with interquartile range as appropriate. Receiver operating characteristic curves were generated to identify hemodynamic cut-points. Between groups, 2-sided comparisons for continuous/ordinal variables were made with the Student *t* test or Mann-Whitney *U* test as appropriate. Categorical variables were compared by χ^2 or Fisher exact tests as appropriate. Variables with a *P* < .10 in these uni-

variate analyses were simultaneously entered into multivariate regression models to identify which were independent predictors of outcome. We used binary logistic regression models with significance set as *P* < .05. Statistical analyses were performed by using SPSS Statistics, Version 23 (IBM, Armonk, New York).

RESULTS

Two hundred fifty-six patients meeting the selection criteria were included in the analysis. The mean age of the study population was 65.2 ± 15.4 years, and the mean NIHSS score was 17.3 ± 5.9 . Table 1 presents the clinical characteristics and procedural variables of the groups with good and poor outcomes at 90 days. The groups had similar procedure durations and times from last known healthy to groin puncture, as well as similar rates of IV tPA and stent retriever use. We observed differences in ASPECTS and NIHSS scores and rates of parenchymal hemorrhage between the groups. The poor outcome group also had higher rates of atrial fibrillation and ICA terminus occlusion.

Table 2 shows systolic blood pressure and MAP parameters in the population and their association with outcome. Patients included in the analysis had a mean baseline systolic blood pressure of 157.6 ± 29.3 mm Hg and a MAP of 108.5 ± 18.6 mm Hg. The means for the lowest recorded systolic blood pressure and MAP before successful reperfusion were 118.0 ± 22.0 and 80.7 ± 14.4 mm Hg, respectively. Baseline pressures did not differ between the 2 outcome groups, but all variables related to the lowest pressure before reperfusion were statistically different (Table 2).

Due to collinearity, we incorporated the continuous variables of the lowest MAP, absolute MAP drop, and percentage MAP drop one at a time into binary logistic regression models for predictors of poor outcome. Neither absolute MAP drop nor percentage MAP drop were independent predictors of outcome (*P* = .38 and .16, respectively). The lowest MAP before modified TICI 2b/3 reperfusion was independently associated with poor outcome (*P* = .04). We performed a linear transformation $[(100 - \text{lowest MAP})/10]$ to place this result in a more meaningful clinical context. As shown in Table 3, the odds of poor outcome increased by 28% for every 10 mm Hg that the lowest MAP fell below 100 mm Hg.

We next generated receiver operating characteristic curves to investigate hemodynamic thresholds that could predict neurologic outcome (Fig 1). The areas under the curve for the MAP variables were approximately 0.6, suggesting that they are weaker predictors than the NIHSS score (0.74) or ASPECTS (0.65). For ease of comparison, we linked the pressures to the mRS category that generated curves above the reference line. For example, a lowest MAP of >90 mm Hg was $>80\%$ specific for good outcome (Fig 1A), whereas a drop in MAP of >40 mm Hg was approximately 80% specific for poor outcome (Fig 1B). The trade-off for the high specificities of these extreme values is low sensitivity. The 30% sensitivity of a lowest MAP of >90 mm Hg indicates that many patients whose MAP falls below 90 mm Hg will still have a good outcome.

In multivariate analysis for predictors of poor outcome, the lowest MAP of <85 mm Hg had an OR of 2.23 (95% CI, 1.09–17.7; *P* = .03). The lowest MAP cutoffs of 70 and 80 mm Hg were also independent predictors (OR = 2.15; 95% CI, 1.02–4.56; *P* = .04; and OR = 2.21; 95% CI, 1.12–4.16; *P* = .02, respectively). For blood pressure changes, an absolute MAP drop of >15 mm Hg

was independently associated with poor outcome (OR = 2.33; 95% CI, 1.11–18.6; P = .03). Finally, the largest OR for poor outcome was 4.38 for a MAP drop of >10% (95% CI, 1.53–12.6; P < .01).

Because the lowest MAP predicted an outcome over a range of cutoffs, we next examined how its effect varied by the baseline NIHSS score. Given our sample size, we divided our study population into 3 groups by baseline NIHSS. Subdividing these by the lowest MAP yielded subgroups of 18–26 patients. The rates of

good outcome are shown in Fig 2. For less severe strokes (NIHSS score, <15), even patients whose MAP fell below 70 mm Hg had a 78% rate of good outcome. Only 60% of patients with NIHSS scores of ≥15 had good outcomes, even when their MAPs stayed above 90 mm Hg.

DISCUSSION

The optimal hemodynamic management of patients undergoing endovascular therapy for acute ischemic stroke remains a topic of debate among clinicians. The 2014 Society for Neuroscience in Anesthesiology and Critical Care Expert Consensus Statement recommends the use of continuous hemodynamic monitoring with maintenance of systolic blood pressure at 140–180 mm Hg,⁸ but these recommendations are not based on data from patients having undergone thrombectomy. Instead, they originate from large epidemiologic studies that examined the associations between poor outcome and baseline hemodynamics or variation during the acute phase of acute ischemic stroke.^{9–11} Davis et al³ have investigated the association between favorable neurologic outcome and the lowest systolic blood pressure of >140 mm Hg based on the same extrapolation. In a subsequent study, our group selected a threshold of MAP of >70 mm Hg after dividing our range of observed MAP into quartiles.⁴ Most recently, Löwhagen Hendén et al¹² showed that a >40% fall in MAP during endovascular reperfusion with the patient under general anesthesia is an independent predictor of poor neurologic outcome. We saw a need to more closely examine how various blood pressure changes influence outcome for patients undergoing thrombectomy.

We sought to perform our analysis in a large but relatively homogeneous study population to best observe the relationship between intraprocedural hypotension and outcome. We chose to restrict our analysis to those patients who achieved successful reperfusion (modified TICI 2b/3) because even the best blood pressure control would be unlikely to improve outcome if the vessel remained occluded. Because hypotension has been shown to be collinear with general anesthesia,³ we restricted our analysis to those patients whose procedures were performed under MAC to eliminate confounding by anesthesia type.

Despite the perceived hemodynamic stability of thrombec-

tomy with the patient under sedation, we observed substantial drops in blood pressure during the procedures. Our baseline and lowest pressures are similar to the MAC/sedation cohorts reported from the Cleveland Clinic ($n = 99$)¹³ and Mayo Clinic ($n = 38$).¹⁴ Rates of vasopressor use were also quite similar across the 3 studies. The results from these 3 institutions suggest that it is difficult to replicate the tight hemodynamic control in the Calgary cohort reported by Davis et al.³ One potential reason might be differences in the depth of sedation or drugs used. Although the former is impossible to determine, we can make crude comparisons of the latter. The Calgary patients received only fentanyl and midazolam for sedation, whereas our institution uses dexmedetomidine infusions with supplemental fentanyl and midazolam if needed. The practice at the Cleveland Clinic mirrors ours except they also use propofol infusions.¹³ In contrast, most patients at the Mayo Clinic received only fentanyl and midazolam for sedation but still experienced significant drops in blood pressure.¹⁴ It

therefore appears that no particular sedative regimen can ensure tight hemodynamic control.

Not only are blood pressure drops common during MAC, but even modest drops in blood pressure can have a dramatic impact on neurologic outcome. This is perhaps best illustrated by our finding that a decrease in MAP from baseline of $>10\%$ carries an OR for poor outcome of 4.38. Such tight hemodynamic control may not always be possible, but it should be a goal even with the patient under minimal sedation. From the receiver operating characteristic curves and multivariate models, we found no single MAP threshold. Instead, the lowest MAP showed a dose effect in which each 10-mm Hg drop below 100 mm Hg increased the odds of poor outcome. Although we consistently observed the benefit of keeping the MAP close to baseline, the critical MAP threshold may vary by the severity of the underlying stroke. Patients with an NIHSS score of <15 had high rates of good outcome across a wide range of MAPs, whereas the lowest MAP below 80 mm Hg had a large outcome effect for those with NIHSS scores of >20 . For those patients in the middle (NIHSS score, 15–20), the threshold appeared to be 70 mm Hg. Presumably, in a homogeneous cohort of large-vessel occlusion strokes, patients with higher NIHSS severity have poorer collaterals and, thus, are more dependent on blood pressure compared with patients with milder stroke severity.

Low blood pressure has been reported to be an independent risk factor for poor outcome in 2 mixed populations of MAC and patients under general anesthesia^{3,4} and 1 pure general anesthesia group.¹² We found that this relationship holds true even in populations with no general anesthesia. What remains unknown, however, is whether intervention to correct hypotension can actually improve outcomes. One group recently reported their experience instituting hemodynamic parameters for their patients undergoing thrombectomy.¹⁵ They noted similar blood pressures in the groups with poor and favorable outcomes but that the cumulative dose of norepinephrine was independently associated with poor outcome.¹⁵ These data raise the possibility that vasopressors may improve peripheral blood pressures without improving blood flow to the ischemic penumbra. Future work might approach this question through a prospective, randomized trial evaluating strict blood pressure control by using vasopressors in comparison with usual anesthesia care. Until the results of such a trial are available, it seems reasonable to minimize hypotension during endovascular thrombectomies for acute ischemic stroke.

The present study has several limitations. Although larger than the previous studies, it remains retrospective in nature. As with all such studies, missing data may bias the results in unpredictable ways. For

Table 3: Binary logistic regression model for poor neurologic outcome (90-day mRS > 2)^a

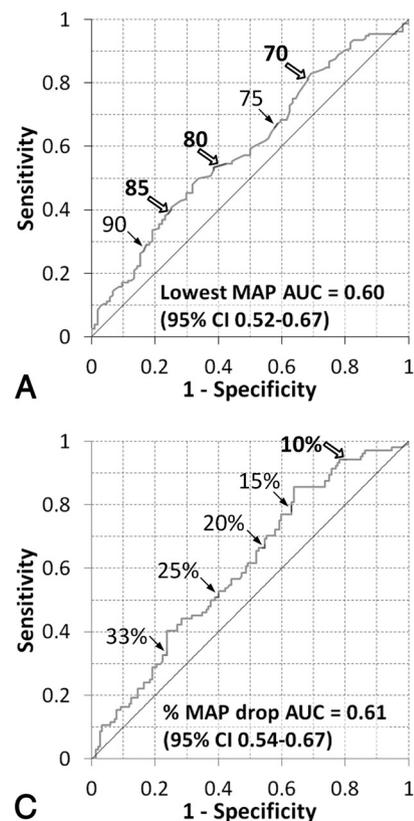

FIG 1. Receiver operating characteristic curves for changes in MAP before modified TICI 2b/3 reperfusion. Curves are shown for the effect of the lowest MAP on 90-day mRS 0–2 (A) and for the relationship between mRS 3–6 and an absolute MAP drop (B) and percentage MAP drop (C). The curves are labeled with pressures (A and B, in millimeters of mercury) and percentages (C). The cutoffs that were independent predictors of outcome in binary regression models are shown with **bold type** and **open block arrows**. AUC indicates area under the curve.

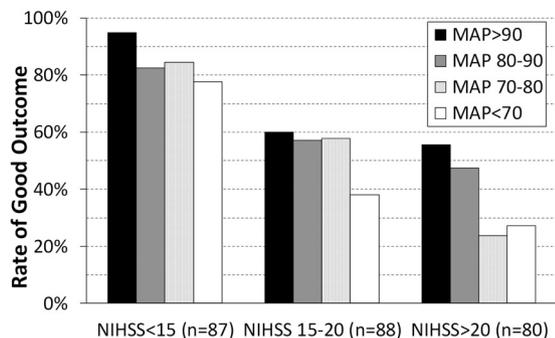

FIG 2. Rates of good neurologic outcome (90-day mRS of 0–2) by baseline NIHSS score and the lowest MAP measured before modified TICI 2b/3 reperfusion. Subdividing the NIHSS groups into 4 MAP categories yielded subgroups of similar size ($n = 18–26$).

example, we did not collect prestroke mRS scores. The lowest blood pressures before reperfusion were captured from the anesthesia records as the lowest MAP rather than lowest systolic pressure. However, our rationale was that most blood pressure data were acquired by using noninvasive oscillometric cuff sphygmomanometers, which measure the MAP and derive systolic and diastolic pressures from an algorithm.⁷ Additionally, our choice of a study population with minimal confounders may limit the generalizability of our results to other patients undergoing thrombectomy, such as those with posterior circulation stroke or patients receiving general anesthesia. Nevertheless, the hemodynamic variables we identified may provide a useful way to control for the effect of hypotension in future studies on the effect of anesthesia on outcome.

CONCLUSIONS

Significant decreases in blood pressure occur during thrombectomies performed under MAC sedation. Our data support the hypothesis that hypotension influences outcome in patients not exposed to general anesthesia. Every 10-mm Hg drop in MAP below 100 mm Hg before reperfusion increased the odds of poor outcome by an estimated 28% (95% CI, 1%–62%). Even a 10% drop in MAP from the initial value seen in the angiography suite was a strong independent risk factor for poor outcome. These results suggest that clinicians should be just as vigilant in maintaining blood pressure for patients under MAC or conscious sedation as they are for those under general anesthesia.
