3D Pseudocontinuous Arterial Spin-Labeling MR Imaging in the Preoperative Evaluation of Gliomas

Q. Zeng, B. Jiang, F. Shi, C. Ling, F. Dong, and J. Zhang

BACKGROUND AND PURPOSE: Previous studies showed conflicting results concerning the value of CBF maps obtained from arterial spin-labeling MR imaging in grading gliomas. This study was performed to investigate the effectiveness of CBF maps derived from 3D pseudocontinuous arterial spin-labeling in preoperatively assessing the grade, cellular proliferation, and prognosis of gliomas.

MATERIALS AND METHODS: Fifty-eight patients with pathologically confirmed gliomas underwent preoperative 3D pseudocontinuous arterial spin-labeling. The receiver operating characteristic curves for parameters to distinguish high-grade gliomas from low-grade gliomas were generated. Pearson correlation analysis was used to assess the correlation among parameters. Survival analysis was conducted with Cox regression.

RESULTS: Both maximum CBF and maximum relative CBF were significantly higher in high-grade gliomas than in low-grade gliomas \((P < .001)\). The areas under the curve for maximum CBF and maximum relative CBF in distinguishing high-grade gliomas from low-grade gliomas were 0.828 and 0.863, respectively. Both maximum CBF and maximum relative CBF had no correlation with the Ki-67 index in all subjects and had a moderate negative correlation with the Ki-67 index in glioblastomas \((r = −0.475, −0.534\), respectively\). After adjustment for age, a higher maximum CBF \((P = .008)\) and higher maximum relative CBF \((P = .005)\) were associated with worse progression-free survival in gliomas, while a higher maximum relative CBF \((P = .033)\) was associated with better overall survival in glioblastomas.

CONCLUSIONS: 3D pseudocontinuous arterial spin-labeling–derived CBF maps are effective in preoperative evaluation of gliomas. Although gliomas with a higher blood flow are more malignant, glioblastomas with a lower blood flow are likely to be more aggressive.

ABBREVIATIONS: ASL = arterial spin-labeling; CASL = continuous ASL; GBM = glioblastoma; HGG = high-grade glioma; HR = hazard ratio; KPS = Karnofsky Performance Scale; LGG = low-grade glioma; max = maximum; OS = overall survival; pCASL = pseudocontinuous ASL; PFS = progression-free survival; ROC = receiver operating characteristic; WHO = World Health Organization

Glioma is the most common intracranial malignant tumor, accounting for almost 80% of primary malignant brain tumors.\(^1\) Grading of gliomas is important for an optimal therapy plan and predicting outcome.\(^2,3\) According to the World Health Organization (WHO) criteria, gliomas can be classified into 4 groups: grades I–IV. Grade I and grade II gliomas are considered low-grade gliomas (LGGs), while grade III and grade IV gliomas are regarded as high-grade gliomas (HGGs).

Advanced MR imaging techniques, such as MR perfusion, have been shown to be more effective than conventional MR imaging techniques in grading gliomas.\(^4,5\) Dynamic susceptibility contrast perfusion imaging is the reference standard for evaluating tumor perfusion.\(^6,7\) However, this technique relies on the intravenous application of a contrast medium, which is not suitable for patients who are allergic to this medium or who have renal failure.\(^8,9\)

Arterial spin-labeling (ASL) is a noninvasive MR perfusion imaging technique for obtaining CBF maps. Some previous studies based on pulsed ASL and continuous ASL (CASL) have shown that the ASL-derived CBF maps have potential value in grading gliomas\(^10-15\) and predicting their progression.\(^9,16,17\) However, although pseudocontinuous ASL (pCASL) is considered an improved method over pulsed ASL and CASL,\(^18-20\) a recent study reported that pCASL-derived CBF maps failed to accurately grade gliomas.\(^21\)
On the other hand, according to many previous studies, gliomas with higher tumor blood flow are commonly more malignant.\textsuperscript{8-17} However, a recent study found a positive correlation between proliferation activity and levels of a hypoxia biomarker in glioblastoma (GBM),\textsuperscript{23} suggesting that GBM with a lower blood flow might be more aggressive. Hence, the correlation between relative CBF and the grade of malignancy might be more complex in gliomas.

The purpose of this study was to examine the value of the CBF maps derived from 3D pCASL in preoperatively assessing the grade, cellular proliferation, and prognosis of gliomas. Additionally, we performed a subgroup analysis on patients with GBM.

MATERIALS AND METHODS

Patients

This was a retrospective study based on data collected from our prospective cohort of patients with gliomas who were hospitalized at the Department of Neurosurgery, Second Affiliated Hospital of Zhejiang University School of Medicine, between August 2013 and January 2015. This study was approved by the local ethics review board and was conducted in accordance with the ethical principles of the Declaration of Helsinki. Written informed consent was obtained from all participants. Fifty-eight patients with supratentorial cerebral gliomas, who underwent a preoperative MR imaging examination with a 3D pCASL sequence, were enrolled in this study. The preoperative Karnofsky Performance Scale (KPS) was administered in all patients when they were admitted to the hospital.

Imaging Data Acquisition

All subjects underwent MR imaging on a 3T system (Discovery MR750; GE Healthcare, Milwaukee, Wisconsin) with an 8-channel high-resolution receiver head coil. The CBF images were acquired with a 3D pCASL sequence with the following parameters: section thickness, 4 mm; number of sections, 56; FOV, 240 $\times$ 240 mm; matrix, 128 $\times$ 128; TR, 4632 ms; TE, 10.5 ms; flip angle, 111°; number of excitations, 3; labeling duration, 1450 ms; postlabeling duration, 1525 ms; and pixel bandwidth, 976.6 Hz/pixel. The scan time for this sequence was 4 minutes 29 seconds. In addition, a contrast-enhanced T2-FLAIR sequence was acquired after the in-time for this sequence was 4 minutes 29 seconds. In addition, a duration, 1525 ms; and pixel bandwidth, 976.6 Hz/pixel. The scan

The median time interval between preoperative MR imaging and admission only stereotactic biopsy, and the others underwent craniotomy. The histopathologic diagnosis was performed by pathologists on the basis of the WHO 2007 criteria. The purpose of this study was to examine the value of the CBF maps derived from 3D pCASL in preoperatively assessing the grade, cellular proliferation, and prognosis of gliomas. Additionally, we performed a subgroup analysis on patients with GBM.

Follow-Up

Three patients who underwent stereotactic biopsy and 2 patients who died of operative complications were excluded in the post-operative follow-up. Among the other 53 patients, only 2 (3.9%) were lost to follow-up. Thus, 51 patients were included in the survival analysis. The median follow-up time was 30 months (range, 24–36 months). Overall survival (OS) was defined as the time from diagnosis until either death or the time the patient was last known to be alive (censored), and progression-free survival (PFS) was defined as the time from diagnosis until tumor progression, recurrence, or death or when the patient was last known to be alive (censored).\textsuperscript{25}

Image Processing and Analysis

The CBF images were all coregistered to the contrast-enhanced T2-FLAIR images by using SPM12 (www.fil.ion.ucl.ac.uk/spm). The analysis of the images was performed with ImageJ, Version 1.49 (National Institutes of Health, Bethesda, Maryland). The ROIs were manually placed on the contrast-enhanced T2-FLAIR images by 1 expert neuroradiologist with 20 years’ experience, who was blinded to the pathology of the tumors. Before ROIs were drawn, the image section that was speculated to contain the tumor area with the highest tumor blood flow was chosen by referring to the CBF maps. Areas with an abnormal signal in the enhanced T2-FLAIR images were all included. Another rectangular ROI was drawn to include contralateral gray matter areas. Then ROIs were copied to the corresponding CBF maps, as shown in Fig 1. The maximum CBF values (CBF\textsubscript{max}) in ROIs were obtained. Then the relative CBF\textsubscript{max} (rCBF\textsubscript{max}) was calculated by dividing the CBF\textsubscript{max} in the tumor ROI by the CBF\textsubscript{max} in the contralateral ROI.

Interobserver Concordance

Another reader, a junior neurosurgeon who was blinded to the pathology, also delineated the ROIs of all tumors. The measurements from this reader were only used for the assessment of interobserver concordance. The rCBF\textsubscript{max} values measured by the 2 readers were compared by means of an intraclass correlation coefficient.

Statistical Analysis

All statistical analyses were performed with SPSS Statistics, Version 22 (IBM, Armonk, New York) and GraphPad Prism, Version 6.0 (GraphPad Software, San Diego, California). The significance level was set to $\alpha = .05$. $P < .05$ was statistically significant.

The normality assumption was tested with the Kolmogorov-Smirnov test. The data were expressed as mean ± SD. Interobserver reliability was with the intraclass correlation coefficient based on a 2-way random-effects model. The Pearson correlation analysis was used to assess the correlation among parameters.

The 1-way ANOVA followed by the Fisher least significant difference test was used to compare differences in parameters among multiple groups. The differences in parameters between the HGG and the LGG groups were compared using the independent samples t test. The receiver operating characteristic (ROC) curves for parameters in distinguishing HGG from LGG were generated. Optimal cutoff values were derived from ROC curves, and sensitivity, specificity, predictive values, and accuracy were calculated on the basis of these best cutoff values.

Survival analysis was conducted with the Cox regression for
both the univariate and multivariate analyses. Except for CBF parameters, 3 clinical features (age, sex, preoperative KPS) were also included in the survival analysis.

RESULTS

Patient Characteristics

Among these 58 patients with gliomas, there were 27 women and 32 men, with a mean age of 49.3 years (range, 26–76 years) and a mean KPS score of 82.9 (range, 30–100). According to the WHO 2007 criteria, there were 13 patients diagnosed with WHO grade II (astrocytomas, n = 5; oligoastrocytomas, n = 4; oligodendrogliomas, n = 4), 17 patients diagnosed with WHO grade III (anaplastic astrocytomas, n = 6; anaplastic oligoastrocytomas, n = 7; anaplastic oligodendrogliomas, n = 4), and 28 patients diagnosed with WHO grade IV (GBM, n = 28).

Interobserver Concordance

The manifestations of an LGG, a GBM with a low Ki-67 index, and a GBM with a high Ki-67 index in contrast-enhanced T2-FLAIR images and CBF maps are shown in Fig 1. Our evaluation of the interobserver concordance for parameters showed excellent agreement. The intraclass correlation coefficients for the measurement of tumor CBFmax, contralateral CBFmax, and rCBFmax were as high as 0.995, 0.860, and 0.987, respectively. Furthermore, there was a very strong correlation between CBFmax and rCBFmax (r = 0.941).

Parameters in Each Type of Pathologic Tumor

The measured parameters in each type of pathologic tumor are summarized in Table 1. The CBFmax of GBMs was only significantly higher than that of astrocytomas (P = .002) and oligoastrocytomas (P = .005), while the rCBFmax of GBMs was significantly higher than that of astrocytomas (P < .001), oligoastrocytomas (P < .001), oligodendrogliomas (P = .032), anaplastic astrocytomas (P = .03), and anaplastic oligoastrocytomas (P = .027). Both the CBFmax and rCBFmax of GBMs were lower than those of anaplastic oligodendrogliomas without statistical significance (both P = .22).

Both the CBFmax and rCBFmax of anaplastic oligodendrogliomas were significantly higher than those of anaplastic astrocytomas (P = .035 and .013, respectively) and anaplastic oligoastrocytomas (P = .027 and .012, respectively), while those of oligodendrogliomas were higher than those of astrocytomas (P = .4 and .35, respectively) and oligoastrocytomas (P = .42 and .30, respectively) without statistical significances. Both the CBFmax and rCBFmax of anaplastic oligodendrogliomas were significantly higher than those of oligodendrogliomas (P = .021 and .012, respectively).

The mean CBFmax and rCBFmax were similar between astrocytomas and oligoastrocytomas, or between anaplastic astrocytomas and anaplastic oligoastrocytomas. No significant differences were detected among different pathologic types for contralateral CBFmax (P = .50).

Parameters in Each Tumor Grade

Both the absolute tumor CBFmax and rCBFmax increased with an increase in grade of glioma, as shown in Table 2. In all gliomas, both the CBFmax and rCBFmax of grade IV gliomas were significantly

FIG 1. Enhanced T2-FLAIR images (A, C, and E) and CBF maps (B, D, and F) of a 69-year-old man with oligoastrocytoma (WHO grade II; Ki-67 index, 10%), a 42-year-old man with glioblastoma (WHO grade IV; Ki-67 index, 20%), and a 43-year-old man with glioblastoma (WHO grade IV; Ki-67 index, 60%), respectively. Note that blood flow is significantly elevated in the glioblastoma with a relatively low Ki-67 index, while it is not elevated in the glioblastoma with a very high Ki-67 index. The unit for CBF maps is milliliters/100 g/min.
higher than those of grade II gliomas (P < .001), and those of grade III gliomas were significantly higher than those of grade II gliomas (P = .011 and .009, respectively), while those of grade IV gliomas were higher than those of grade III gliomas without statistical significance (P = .198 and .070, respectively). After oligodendrogliomas and anaplastic oligodendrogliomas were excluded, significant differences between grade III gliomas and grade IV gliomas were detected for both $CBF_{\text{max}}$ and $rCBF_{\text{max}}$ (P = .025 and .004, respectively).

### Differentiation of LGG and HGG

There were significant differences between LGG and HGG for both $CBF_{\text{max}}$ and $rCBF_{\text{max}}$ ($P < .01$), regardless of whether oligodendrogliomas and anaplastic oligodendrogliomas were excluded, as shown in Fig 2. The ROC curves for $CBF_{\text{max}}$ and $rCBF_{\text{max}}$ in distinguishing HGG from LGG are shown in Fig 3, both $CBF_{\text{max}}$ and $rCBF_{\text{max}}$ ($P < .001$), compared with grade II.

### Correlation with the Ki-67 Index

In all patients, as shown in Fig 4, both $CBF_{\text{max}}$ ($P = .565$) and $rCBF_{\text{max}}$ ($P = .652$) values were not correlated with the Ki-67 index. However, there was a moderate positive association between $CBF_{\text{max}}$ and the Ki-67 index in the low Ki-67 index group ($P = .029, r = .399$), and a high inverse association between $CBF_{\text{max}}$ and the Ki-67 index in the high Ki-67 index group ($P = .17, r = .432$) and a high inverse correlation with the Ki-67 index in the high Ki-67 index group ($P < .001, r = -.784$). In GBMs, both $CBF_{\text{max}}$ ($P = .017, r = -.475$) and $rCBF_{\text{max}}$ ($P = .006, r = -.534$) showed a moderate negative correlation with the Ki-67 index.

### Survival Analysis

Fifty-one patients (13 grade II, 13 grade III, 25 grade IV) were included in the survival analysis. Table 4 shows the results obtained with the univariate Cox model for PFS and OS in both gliomas and GBMs. Sex had no association with PFS or OS in both gliomas and GBMs (all data, $P > .5$). In gliomas, higher $CBF_{\text{max}}$ and higher $rCBF_{\text{max}}$ were associated with worse PFS (hazard ratio [HR] = 1.005, 1.670, 1.036, 0.971, respectively; all data, $P < .05$), while $CBF_{\text{max}}$ and $rCBF_{\text{max}}$ were not prognosis factors for OS ($P = .244$ and .322, respectively). In GBMs, lower $CBF_{\text{max}}$ and $rCBF_{\text{max}}$ tended to be associated with worse OS without statistical significances ($HR = 0.993, 0.563, 1.030$, respectively; $P = .070$ and .103, respectively), while $CBF_{\text{max}}$ and $rCBF_{\text{max}}$ were not associated with PFS ($P = .947$ and .644, respectively).

Either $CBF_{\text{max}}$ or $rCBF_{\text{max}}$ were included in the multivariate Cox analysis for PFS in gliomas, together with age and KPS. Furthermore, $CBF_{\text{max}}$ or $rCBF_{\text{max}}$ were also included in the multivariate Cox analysis for OS in GBM, together with age. The results showed that $rCBF_{\text{max}}$ was a significant independent prognostic factor for PFS in gliomas.

(P = .005) and OS in GBMs (P = .033), while CBF_{max} was only a significant independent prognosis factor for PFS in gliomas (P = .008), shown in Table 5. After adjustment for age, higher CBF_{max} (HR = 1.007) and higher rCBF_{max} (HR = 1.707) were associated with worse PFS in gliomas, while higher rCBF_{max} (HR = 0.490) was associated with better OS in GBM.

DISCUSSION
In this study, 3D pCASL-derived CBF maps were found to be effective in preoperatively assessing the grade and prognosis in gliomas. Another interesting finding was that CBF_{max} and rCBF_{max} showed a dual relationship with the degree of malignancy in gliomas. In accordance with previous studies based on pulsed ASL and CASL,8-17 both CBF_{max} and rCBF_{max} obtained from pCASL increased with increasing grade of gliomas, and gliomas with higher CBF_{max} and rCBF_{max} were associated with worse PFS. These findings suggest that gliomas with higher rCBF_{max} are associated with a higher degree of malignancy. However, in GBMs, both CBF_{max} and rCBF_{max} were found to have a significant negative correlation with the Ki-67 index. Also, GBMs with a lower rCBF_{max} were associated with worse OS after adjustment for age. Thus, GBMs with lower blood flow seemed to be more aggressive.

Unlike quantification methods of DSC MR imaging, which require an accurate arterial input function, 1 advantage of the ASL sequence is that it can provide an absolute quantification of CBF.9 In our study, a very strong correlation between CBF_{max} and rCBF_{max} was reported. The results of rCBF_{max} were similar to those of CBF_{max} in grading gliomas and evaluating the Ki-67 index, while rCBF_{max} seemed to be more valuable in predicting the prognosis of gliomas and GBMs. These results suggest that ASL-derived absolute CBF is also useful in evaluating gliomas.

However, compared with the DSC perfusion MR imaging, one limitation of the application of ASL is the relatively low SNR.15,20

**DISCUSSION**

In this study, 3D pCASL-derived CBF maps were found to be effective in preoperatively assessing the grade and prognosis in gliomas. Another interesting finding was that CBF_{max} and rCBF_{max} showed a dual relationship with the degree of malignancy in gliomas. In accordance with previous studies based on pulsed ASL and CASL,8-17 both CBF_{max} and rCBF_{max} obtained from pCASL increased with increasing grade of gliomas, and gliomas with higher CBF_{max} and rCBF_{max} were associated with worse PFS. These findings suggest that gliomas with higher rCBF_{max} are associated with a higher degree of malignancy. However, in GBMs, both CBF_{max} and rCBF_{max} were found to have a significant negative correlation with the Ki-67 index. Also, GBMs with a lower rCBF_{max} were associated with worse OS after adjustment for age. Thus, GBMs with lower blood flow seemed to be more aggressive.

Unlike quantification methods of DSC MR imaging, which require an accurate arterial input function, 1 advantage of the ASL sequence is that it can provide an absolute quantification of CBF.9 In our study, a very strong correlation between CBF_{max} and rCBF_{max} was reported. The results of rCBF_{max} were similar to those of CBF_{max} in grading gliomas and evaluating the Ki-67 index, while rCBF_{max} seemed to be more valuable in predicting the prognosis of gliomas and GBMs. These results suggest that ASL-derived absolute CBF is also useful in evaluating gliomas.

However, compared with the DSC perfusion MR imaging, one limitation of the application of ASL is the relatively low SNR.15,20

**FIG 3.** Receiver operating characteristic curves of CBF_{max} (A) and rCBF_{max} (B) in distinguishing high- from low-grade gliomas, without (black line) or with (red line) oligodendrogliomas and anaplastic oligodendrogliomas excluded.

**FIG 4.** The linear regression of CBF_{max} (A–C) and rCBF_{max} (D–F) with the Ki-67 index in all subjects (A and D), in the low and high Ki-67 groups (B and E), and in glioblastomas (C and F). The low Ki-67 group included patients with a Ki-67 index of <30%, and the high Ki-67 group included patients with a Ki-67 index of ≥30%.

a With oligodendrogliomas and anaplastic oligodendrogliomas excluded.
CASL is an improved method, providing a higher tagging efficiency compared with pulsed ASL. However, because of magnetization transfer effects, the magnetization in the target tissues will be reduced, which limits the application of this method. In 2005, García et al proposed the pCASL method to overcome this disadvantage, and this method can improve not only the SNR but also the accuracy of CBF measurements. Previous studies have shown that the pulsed ASL- derived and CASL-derived CBF maps have potential value in grading gliomas. In the current study, pCASL-derived CBF maps were also found to be effective in grading gliomas. However, a previous study indicated that in previous studies based on relative CBV, the ability of the CBFmax and rCBFmax values in differentiating HGGs from LGGs improved after we excluded oligodendrogliomas and anaplastic oligodendrogliomas.

Furthermore, our results demonstrated a significantly higher CBFmax and rCBFmax in anaplastic oligodendrogliomas than in oligodendrogliomas. These results conflicted with those of a previous study based on CASL-derived CBFmax. However, a recent study by Fellah et al, based on DSC-derived relative CBF, reported a result similar to that in our study. Several previous studies have also shown a significantly higher relative CBV in anaplastic oligodendrogliomas than in oligodendrogliomas, while some other studies have reported a conflicting result. The ability of perfusion parameters to distinguish oligodendrogliomas and anaplastic oligodendrogliomas needs to be evaluated further.

A previous study by Mayer et al showed a positive correlation between proliferative activity and the level of a hypoxia biomarker in GBM. This molecular pathology finding is consistent with our finding that the Ki-67 index had a negative correlation with CBFmax and rCBFmax in GBMs. However, the potential mechanism is not clear. Evans et al found that higher grade gliomas were associated with more hypoxia. It is widely accepted that hypoxia will lead to the activation of the transcription of hypoxia-inducible factor-1 via stabilization of its α subunit. One potential mechanism of this may result in lower tumor blood flow in GBMs, which causes severe hypoxia and, in turn, the activation of the transcription of hypoxia-inducible factor-1, leading to high proliferative activity through further downstream pathways. Another potential mechanism might be due to the inability of angiogenesis to keep up with tumor cell proliferation in certain GBMs that have a high proliferative activity. The explicit mechanism needs to be investigated further.

On the other hand, our study also found that GBMs with a lower rCBFmax were associated with a worse OS but showed no association with PFS. This finding also suggests that a GBM with lower blood flow may cause severe hypoxia, causing it to become increasingly malignant. Some other studies have also found that hypoxia in GBM is related to a poor prognosis, yet 2 previous studies based on ASL-derived CBF maps have reported a contradictory result. However, 1 of those contradictory studies involved only 18 gliomas, and another contradictory study had only performed qualitative analysis, which reduced their reliability. It is well-known that the activity of hypoxia-inducible factor-1α-mediated pathways due to hypoxia will lead to migration and invasion of tumor cells. In addi-

*KPS was not included in the multivariate Cox analysis for OS in glioblastomas.

Only the P value was presented for the variable, which was excluded from the Cox model with P > 10.
tion, hypoxia is known to induce resistance to radiation therapy and chemotherapy through several mechanisms.42,43 This could explain why GBMs with a lower blood flow were more aggressive and were associated with a worse OS.

However, a previous study by Law et al44 in 2008 found that GBMs with high relative CBV were significantly associated with a poor OS, while another study by Deike et al45 in 2016 suggested that GBMs with a low blood supply may be associated with poor OS. The difference in results between these studies may be due to the different postoperative treatment strategies. Currently, concomitant radiochemotherapy has become the standard treatment for GBMs, and sometimes bevacizumab is also used to treat recurrent GBMs. Thus, resistance to radiation therapy and chemotherapy is now playing a more important role than before in the treatment of GBMs and will clearly influence the OS of patients with GBMs. A prospective study enrolling relatively large samples is needed to accurately evaluate the role of perfusion parameters in predicting the outcome of GBMs.

There were some limitations in our research. First, the sample size used for this study was not very large; therefore, some of the results may not be completely reliable, especially the results from the subgroup analysis. Further studies enrolling larger samples are needed to verify these results. Second, the postcontrast T2-FLAIR images were consulted when drawing the ROIs, so the ROI selection method presented in our study was not an accurate portrayal of a blind study. However, the resulting bias is hardly avoided, and it has also existed in many previous studies.8–14 Compared with previous ROI selection methods, the method presented in our study is relatively objective, with an excellent intraclass correlation coefficient. Third, molecular pathology for gliomas, such as 1p19q deletion and IDH1/2 mutation, was not routinely examined in our study. Further studies dividing gliomas or GBMs into subgroups by molecular pathology may provide further useful information.

CONCLUSIONS

3D pCASL-derived CBF maps are effective in preoperative evaluation of gliomas. Although gliomas with higher blood flow are associated with a higher degree of malignancy, GBMs with a lower blood flow are likely to be more aggressive.
