In Vivo Imaging of Venous Side Cerebral Small-Vessel Disease in Older Adults: An MRI Method at 7T

ABSTRACT

BACKGROUND AND PURPOSE: Traditional neuroimaging markers of small-vessel disease focus on late-stage changes. We aimed to adapt a method of venular assessment at 7T for use in older adults. We hypothesized that poorer venular morphologic characteristics would be related to other small-vessel disease neuroimaging markers and a higher prevalence of small-vessel disease–Alzheimer disease risk factors.

MATERIALS AND METHODS: Venules were identified in periventricular ROIs on SWI and defined as tortuous or straight. The tortuosity ratio was defined as total tortuous venular length divided by total straight venular length. White matter hyperintensity burden (visually rated from 0 to 3) and the number of microbleeds (0, 1, >1) were determined. Differences in tortuous and straight venular lengths were evaluated. Relationships with demographic variables, allele producing the e4 type of apolipoprotein E (APOE4), growth factors, pulse pressure, physical activity, and Modified Mini-Mental State Examination were assessed via Spearman correlations.

RESULTS: Participants had 42% more tortuous venular tissue than straight (median, 1.42; 95% CI, 1.13–1.62). APOE4 presence was associated with a greater tortuosity ratio (p = 0.454, P = .001), and these results were robust to adjustment for confounders and multiple comparisons. Associations of the tortuosity ratio with sex and vascular endothelial growth factor did not survive adjustment. Associations of the tortuosity ratio with other variables of interest were not significant.

CONCLUSIONS: Morphologic measures of venules at 7T could be useful biomarkers of the early stages of small-vessel disease and Alzheimer disease. Longitudinal studies should examine the impact of apolipoprotein E and vascular endothelial growth factor on the risk of venular damage.

ABBREVIATIONS: AD = Alzheimer disease; APOE4 = allele producing the e4 type of apolipoprotein E; BDNF = brain-derived neurotrophic factor; IQR = interquartile range; LIFE MRI = Lifestyle Interventions and Independence for Elders Magnetic Resonance Imaging study; 3MS = Modified Mini-Mental State Examination; SVD = small-vessel disease; VEGF = vascular endothelial growth factor; WMH = white matter hyperintensities

Cerebral small-vessel disease (SVD) increases dementia risk and vulnerability to Alzheimer disease (AD) neuropathology. Neuroimaging methods investigating SVD have traditionally relied on WM hyperintensities (WMHs). However, WMH is a marker of late-stage SVD, reflecting advanced parenchymal damage, reduced CBF, and abnormalities of the small penetrating vessels. Thus, there is a need for radiologic markers that capture the earlier stages of SVD relating directly to vessel health.

With aging and hypertension, arteries have a reduced ability to absorb flow pulsatility, thus transmitting highly pulsatile flow to the venules. Venular walls are well-equipped to handle low pulsatile and slow flow, but not highly pulsatile flow. Pulsatility-related damage can induce venular morphologic changes such as collagenosis, leading to loss of elasticity and lumen narrowing/occlusion, which, in turn, promote ischemia. Both collagenosis and

tortuosity lead to reduced CBF and increased upstream resistance, exacerbating arterial pathology. Extravasation and inflammatory response, including focal perivascular parenchymal infiltration, can also occur, facilitated by the lack of tight junctions on the venous-side circulation. Inflammatory cascades further damage the vasculature, reduce CBF, and compromise the BBB. These phenomena can become apparent as morphologic changes such as tortuosity, collagenosis, and thicker basal lamina. Such changes have been seen in vivo in AD and in postmortem studies, and they appear more common with older age and in proximity to regions with WMHs. Although the possibility has not been tested directly, venular morphologic alterations are considered to precede radiologically overt WMHs.

Ultra-high-field (7T) MR imaging has emerged as a noninvasive method to visualize venous microcirculation. Specifically, SWI exploits the paramagnetic properties of deoxyhemoglobin to visualize venules without a contrast agent. Methods to quantify venules in multiple sclerosis, sickle cell anemia, CADASIL, and, recently, AD have been reported. However, venular characteristics in relation to cerebral SVD in aging are unknown.

Our primary aim was to demonstrate the feasibility of adapting published methods to study venular characteristics in older adults. Our secondary aim was to evaluate the relationships of venular characteristics with neuroimaging markers of SVD—WMH and microbleeds—and variables relevant to SVD and AD. We hypothesized that poorer venular morphologic characteristics would be related to other SVD neuroimaging markers and a higher prevalence of SVD-AD risk factors.

**MATERIALS AND METHODS**

**Participants**

The Lifestyle Interventions and Independence for Elders Magnetic Resonance Imaging study (LIFE MRI) is a neuroimaging study within a randomized controlled trial, which demonstrated that physical activity prevents major mobility disability in at-risk community-dwelling older adults versus health education control (hazard ratio, 0.82, \( P = .03 \)). The study protocol was approved by the University of Pittsburgh institutional review board. All participants provided written informed consent. The present study \( (n = 53) \) used images from the baseline visit.

The LIFE study design has been previously reported. The On-line Table shows inclusion/exclusion criteria. Participants were not screened for MRI imaging on the basis of caffeine use due to minimal reported average caffeine-related signal change of veins in white matter \((-2 \pm 1.2\%)\). On-line Fig 1 shows participant flow.

**Sample Characteristics**

Age, race, and sex, self-reported by participants, were evaluated because of their association with SVD and AD. Apolipoprotein E was genotyped by using TaqMan (TaqMan probe C\(_{\text{a}}\)_904973_10; Applied Biosystems, Life Technologies, Foster City, California) and pyrosequencing. The allele producing the e4 type of apolipoprotein E (APOE4) is the strongest genetic risk factor for late-onset AD. Pulse pressure (systolic blood pressure–diastolic blood pressure; average of 2–seated measurements) and physical activity were assessed because of their associations with AD and SVD. Physical activity was measured for 7 days by using hip-worn accelerometry (GT3X; Actigraph, Pensacola, Florida) as minutes per day of moderate physical activity. Finally, the Modified Mini-Mental State Examination (3MS) was included as a measure of global cognition.

**Growth Factors**

The angiogenic factors vascular endothelial growth factor (VEGF) and brain-derived neurotrophic factor (BDNF) were measured via the Lumineux system with kits (Human Cancer Panel and Neurodegenerative Disease Panel; EMD Millipore, Hercules, California). Fasting blood, collected by venipuncture, remained at room temperature for 30–60 minutes to clot and was then centrifuged at 1600 x g for 15 minutes at 4°C. Serum was aliquoted and immediately frozen at \(-70^\circ\text{C}\) or lower and stored until analysis. Concentrations were determined with 2 sets of standard curves, with final values calculated according to standardized procedures we have validated.

**Potential Confounders**

Self-reported antihypertensive medication use, which may affect pulse pressure, was recorded. Blood hemoglobin level was measured because it may affect venular conspicuity on SWI. We also recorded SWI voxel size, which varied among the participants.

**Outcome Variables**

**Venular Characteristics.** Axial susceptibility-weighted MRIs were obtained at the University of Pittsburgh MR Research Center by using a Rapid Biomedical (Rimpar, Germany) 8-channel head coil on a Siemens (Erlangen, Germany) 7T scanner \( (TR = 2000\text{ ms}, TE = 15\text{ ms}) \), acquired with \( 0.25 \times 0.25 \times 1.50\text{ mm} (n = 40), 0.23 \times 0.23 \times 3.00\text{ mm voxels, interleave gap = 0.60 mm (n = 12), or with 0.50 \times 0.50 \times 1.00\text{ mm voxels (n = 5). When necessary, scans were resampled to 1.50-mm section thickness.} \)

A 4 × 1 cm ROI was placed in each hemisphere, 1 section below the uppermost section on which ventricular CSF was visible. To maintain consistency, we placed the ROI on the basis of native-space landmarks, centered along the anteroposterior length of the ventricle, and on the lateral wall of the ventricle \( (\text{On-line Fig 2}) \). The ROI was chosen because it corresponds to regions known to be vulnerable to SVD, and allows the greatest consistency in vessel orientation, with a clear course perpendicular to the length of the lateral ventricles. The minimum intensity projection was applied over 3 sections \( (4.5\text{ mm}) \) to improve visualization.

Three raters (C.E.S., D.R.J., N.A.M) were trained and overseen by a certified neuroradiologist and the study Principal Investigator. First, published protocols were studied and discussed among the raters, neuroradiologist, Principal Investigator, and coinvestigators. Next, the same 5 MRIs were rated by the raters, each blinded to the tracings of the other 2 raters. Last, each venular tracing was discussed among the raters and with the neuroradiologist and Principal Investigator regarding the presence/absence of the venule and straight/tortuous course. This discussion continued until the raters were proficient in tracing and the results of their consensus were consistent with the judgment of the neuroradiologist/Principal Investigator.
Tracing was done with OsiriX Imaging Software (http://www.osiriX-viewer.com). Criteria to identify a venule were the following: a linear structure of intensity darker than the surrounding parenchyma; length, ≥3 mm; and coursing through the ROI for ≥3 mm (to reduce interrater variability of inclusion for vessels along the edge of the ROI). Most venules could be followed to obvious deep veins, and the dark appearance and orientation axial to the ventricles and deep within the white matter also helped to identify the origin of the vessels as venous. Venules were traced across their full length, even if they continued outside the ROI, to identify the origin of the vessels as venous. Venules were traced and categorized totals as 0, 1, or >1 microbleed.

**Statistical Analysis**

Descriptive statistics were calculated as counts and percentages, means and SDs, or medians and interquartile ranges (IQRs). Differences were tested with t tests, Wilcoxon rank sum tests, or \( \chi^2 \) tests, \( \alpha = .05 \). We also determined the median tortuosity ratio and calculated the 95% CIs by using 10,000 bootstrapped samples.

We explored the relationships of the tortuosity ratio with other neuroimaging markers of SVD, including WMH and microbleeds; nonmodifiable factors, including demographic variables (age, race, and sex), and APOE4; potentially modifiable factors, including growth factors (VEGF and BDNF), pulse pressure, and variables (age, sex, and APOE4), with Spearman correlations, \( \alpha = .10 \). Significant correlations with the tortuosity ratio were re-evaluated as partial correlations adjusted for hemoglobin and voxel size. A false discovery rate of 0.10 was used to correct for multiple comparisons.

Statistical analysis was performed in SAS, Version 9.4, and SPSS version 22.

**RESULTS**

MR imaging study participants were younger and less likely to be non-Hispanic white than the non-MR imaging study participants (Table 1). Of MR imaging study participants, 15/47 with APOE4 data had at least 1 copy of the APOE4 allele. Thus, representation diameter may not have been accurate; thus, we did not quantify diameter.

**White Matter Hyperintensities.** WMH was imaged with T2WI (TR = 12,500 ms, TE = 55 ms, voxel size = 0.5 × 0.5 × 6.0 mm) and MPRAGE (TR = 3430 ms, TE = 3.54 ms, voxel size = 0.7 mm\(^3\) isotropic) and was rated by a consensus of 2 raters (C.R., H.J.A.) with a 0–3 modified Fazekas rating scale.\(^{34} \) Ratings consisted of the following: 0 = none; no punctate hyperintense areas or periventricular rims; 1 = mild: few punctate hyperintense areas and/or limited amount of hyperintense rings around the ventricular horns; 2 = moderate: multiple punctate hyperintense areas and/or larger rims around the ventricular horns; or 3 = severe: confluent subcortical hyperintense areas and/or rings all around the ventricles, including the horns and sides. Only 4/53 had no WMHs (WMH = 0), leaving 92% with at least mild WMHs; thus, we combined 0 and 1 to create a “none/mild” category. Because the distinction between periventricular and deep WMHs is not consistently meaningful, we did not differentiate them.\(^{35} \)

**Microbleeds.** We classified cerebral microbleeds on the basis of Greenberg et al.\(^{36} \) Two trained raters (N.A.M., E.L.T.) characterized microbleeds under the supervision of a neuroradiologist (J.M.). Microbleeds were defined as black or substantially hypointense on SWI, round or ovoid (confirmed on adjacent sections), and at least half surrounded by brain parenchyma. To take advantage of the ability of the 7T magnet to capture quite small microbleeds, we did not use a minimum size criterion. Final ratings were based on consensus, with disagreements mediated by the neuroradiologist. We counted the total number of microbleeds across all 64 sections of the axial SWI and categorized totals as 0, 1, or >1 microbleed.
of APOE4 was higher than the 14% estimate among controls worldwide, but did not differ significantly from non-MR imaging participants. No or mild WMHs were seen in 58.5% of participants, while 20.8% each had moderate and severe WMHs. Regarding microbleeds, 39.6% of the sample had 0, 20.8% had 1, and 24.5% had >1.

The total length of tortuous vessels ranged from 26.25 to 246.36 mm, while the total straight length ranged from 16.72 to 217.65 mm. The overall length of tortuous venules was greater than that of straight venules (Table 2). Total tortuous length was 42% greater than total straight length (median tortuosity ratio, 1.4; 95% bootstrap CI, 1.13–1.62) (On-line Fig 3). To examine whether this finding was due to number of venules or average length, we evaluated differences in those measures. The total number of tortuous venules ranged from 4 to 32, while total straight venules ranged from 2 to 24. There were more tortuous venules than straight ones. The range of average tortuous length was 6.56–10.93 mm, while the range of average straight length was 4.35–11.57 mm, and these average lengths were not significantly different. Thus, the difference in total tortuous and straight venular lengths was driven by a greater number of tortuous venules.

Correlations between neuroimaging markers of SVD and the tortuosity ratio were not significant. WMH correlated at \( p = -0.125, P = .37 \), and microbleeds correlated at \( p = -0.059, P = .70 \). Among nonmodifiable variables associated with AD and SVD, sex was associated with the tortuosity ratio (Table 3). Males had a higher tortuosity ratio (median, 2.15; IQR, 0.98) than females (median, 1.31; IQR, 0.71). Those with at least 1 copy of the APOE4 allele had a higher tortuosity ratio (median, 2.15; IQR, 1.78) than those without it (median, 1.21; IQR, 0.75). Associations with age and race were not significant (\( P > .10 \)).

Among modifiable factors potentially influencing venular characteristics, a higher VEGF was associated with a lower tortuosity ratio. There were no significant associations with BDNF, pulse pressure (adjusted for antihypertensive use), physical activity, or 3MS score (\( P > .10 \)). Results were similar when using a ratio of vessel counts instead of the ratio of total lengths.

The relationship of APOE4 with venular tortuosity, but not the other findings, remained significant after false discovery rate correction of the \( P \) value (\( P = .011 \)). Further adjustment for hemoglobin level and voxel size did not modify the association with APOE4.

### DISCUSSION

We found that application of 7T SWI is feasible to image cerebral venular characteristics in vivo in older adults. This method is a novel way of visualizing an understudied component of the cerebral vasculature. Given associations of venular tortuosity with SVD and AD as well as increases in microvascular changes with age, venular tortuosity may serve as a marker of declining cerebrovascular integrity. This method may afford earlier detection of SVD and has the advantage of characterizing venular morphology without contrast.

We also found that APOE4 was associated with a higher tortuosity ratio, and this association was robust to adjustment for potential confounders and multiple comparisons. This result supports studies implicating APOE4 in reduced vascular integrity.
The APOE4 protein can directly damage the vasculature.\textsuperscript{42} APOE is associated with neuroimaging manifestations of SVD,\textsuperscript{43,44} and there are indications that it is associated with microvascular changes. Mice expressing transgenic human APOE4 have altered basement membrane protein expression.\textsuperscript{45} In humans with AD, APOE4 is associated with membrane protein expression.\textsuperscript{45} APOE4 is associated with both increased deposition and reduced clearance of β amyloid.\textsuperscript{42} Clearly, APOE4 is central to the development of AD pathology, and our results suggest it could be implicated in venular damage. It is possible that β amyloid deposition induces venular damage. An AD mouse model showed that as β amyloid built up in the arterioles beginning at 5 months of age, venular mural cells were damaged by 7 months of age.\textsuperscript{41} However, it is also possible that venular damage induces β amyloid deposition. In this same experimental model, further venular mural cell damage led to increased arteriolar β amyloid deposition and, most interesting, induction of venular tortuosity.\textsuperscript{41} The temporality of venular damage and β amyloid deposition remains an open question. We were unable to collect amyloid imaging. Hence, future multimodal neuroimaging studies need to evaluate the timing and relationship of β amyloid burden and venular tortuosity.

Although our result is remarkably consistent with the proposed APOE4-mediated reduction of vascular integrity,\textsuperscript{42} our study cannot clarify the underlying mechanisms. This limitation notwithstanding, APOE4 being associated with venular tortuosity indicates the potential for risk stratification as an intervention strategy. Thus, other factors should be evaluated to offset APOE4-related risk.

We found a nonsignificant association of the tortuosity ratio with WMHs and microbleeds, which could be due to a lack of sensitivity in our visual ratings or the small sample size. Future larger studies should evaluate associations of the tortuosity ratio with WMH volume, a more sensitive measure compared with visual ratings. Alternatively, this lack of association may indicate that the tortuosity ratio is capturing novel, early information regarding vascular integrity. Future work should examine the relationships of the tortuosity ratio with other SVD neuroimaging markers and related cognitive and mobility impairment and clarify the temporal order of venular damage and other SVD neuroimaging manifestations. We predict that venular damage comes before traditional neuroimaging markers of SVD.

Our study has several limitations. The sample was not selected to have a particularly low or high SVD burden. Future studies should compare venular tortuosity ratios in those 2 groups. Larger samples will be needed to confirm associations with sex and VEGF. The venular measures are also 2D and, therefore, do not account for venules running out of the plane. However, this bias is nondifferential across our sample. Finally, MR imaging participants were younger and had a higher proportion of nonwhites, indicating that this sample may differ from that in the general community-dwelling older adult population.

Despite these limitations, our study has notable strengths. We applied ultra-high-field neuroimaging with a higher SNR than typically used to visualize novel venular characteristics. This allows smaller sample sizes at ultra-high-fields than would be required at lower field strengths. Because this neuroimaging study was also within a randomized controlled trial, these participants were extremely well-characterized, allowing us to control for potential confounding factors.

**CONCLUSIONS**

SWI at 7T offers a noninvasive method to image markers of cerebral venular integrity and fills an important gap in knowledge. Morphologic measures of venules at 7T could be useful biomarkers of the early stages of SVD and AD. Risk and protective factors, especially those that are modifiable, for these pathophysiological changes should be evaluated. Future longitudinal multimodal studies characterizing venular integrity at 7T are warranted.
