Brain MRI Characteristics of Patients with Anti-N-Methyl-D-Aspartate Receptor Encephalitis and Their Associations with 2-Year Clinical Outcome

T. Zhang, Y. Duan, J. Ye, W. Xu, N. Shu, C. Wang, K. Li, and Y. Liu

ABSTRACT

BACKGROUND AND PURPOSE: Anti-N-methyl-D-aspartate receptor encephalitis is an autoimmune-mediated disease without specific brain MRI features. Our aim was to investigate the brain MR imaging characteristics of anti-N-methyl-D-aspartate receptor encephalitis and their associations with clinical outcome at a 2-year follow-up.

MATERIALS AND METHODS: We enrolled 53 patients with anti-N-methyl-D-aspartate receptor encephalitis and performed 2-year follow-up. Brain MRIs were acquired for all patients at the onset phase. The brain MR imaging manifestations were classified into 4 types: type 1: normal MR imaging findings; type 2: only hippocampal lesions; type 3: lesions not involving the hippocampus; and type 4: lesions in both the hippocampus and other brain areas. The modified Rankin Scale score at 2-year follow-up was assessed, and the association between the mRS and onset brain MR imaging characteristics was evaluated.

RESULTS: Twenty-eight (28/53, 53%) patients had normal MR imaging findings (type 1), and the others (25/53, 47%) had abnormal MRI findings: type 2: 7 patients (13%); type 3: seven patients (13%); and type 4: eleven patients (21%). Normal brain MRI findings were more common in female patients (P = .02). Psychiatric and behavioral abnormalities were more common in adults (P = .015), and autonomic symptoms (P = .025) were more common in pediatric patients. The presence of hippocampal lesions (P = .008, OR = 9.584; 95% CI, 1.803–50.931) and relapse (P = .043, OR = 0.111; 95% CI, 0.013–0.930) was associated with poor outcome.

CONCLUSIONS: Normal brain MRI findings were observed in half of the patients. Lesions in the hippocampus were the most common MR imaging abnormal finding. The presence of hippocampal lesions is the main MR imaging predictor for poor prognosis in patients with anti-N-methyl-D-aspartate receptor encephalitis.

ABBREVIATIONS: anti-NMDA = anti-N-methyl-D-aspartate; ICU = intensive care unit; MTA = medial temporal lobe atrophy

Anti-N-methyl-D-aspartate (anti-NMDA) receptor encephalitis was first described by Dalmau et al in 2007 as a common type of autoimmune-mediated limbic encephalitis that presents with various clinical symptoms, including behavioral and psychiatric features, memory and cognitive deficits, seizures, central hypoventilation, and movement disorders. The autoantibody of the anti-NMDA receptor can be detected in the CSF and/or the serum of patients and is a specific antibody that correlates with disease severity. The management of anti-NMDA receptor encephalitis generally includes immunotherapy and tumor detection and removal. First-line immunotherapy (eg, steroids, plasmapheresis, and intravenous immunoglobulins) and second-line immunotherapy, including cyclophosphamide or rituximab, are treatment choices that depend on the individual patient status.
As reported, normal brain MR imaging results were observed in most patients, and 33%–55% of patients showed abnormal brain MR imaging results in several previous publications. Brain lesions often occur in the medial temporal lobe, frontal cortex, and parietal cortex, but lesions in the cerebellum, thalamus, basal ganglia, brain stem, and spinal cord have also been occasionally reported. Additionally, pronounced brain atrophy was observed in 2 patients during a 5- to 7-year follow-up. However, dedicated MR imaging research that focuses on lesion characteristics, especially in Chinese anti-NMDA receptor encephalitis, is lacking, and the associations between the MR imaging characteristics and clinical outcomes remain unknown.

In this study, we systematically investigated the MR imaging features, including lesion location, and the visual rating scale of medial temporal lobe atrophy (MTA) of patients with Chinese anti-NMDA receptor encephalitis and correlated the findings with clinical outcomes as measured by the modified Rankin Scale at a 2-year follow-up.

MATERIALS AND METHODS

Standard Protocol Approvals, Registrations, and Patient Consents

The institutional review board of Xuanwu Hospital approved the study, and written informed consent was obtained from each participant before participation.

Subjects

We consecutively enrolled 54 patients in Xuanwu Hospital, Capital Medical University, Beijing, China, from January 2012 to February 2015; one was excluded because of mortality due to cerebrovascular disease. All patients who tested positive for anti-NMDA receptor antibodies were diagnosed with anti-NMDA receptor encephalitis and showed typical clinical presentations, the usual course of symptom development, as well as CSF and serum that was positive for the associated antibody in tests from 2 independent labs (Tongren Hospital, Capital Medical University, and Peking Union Medical College Hospital in China). Positive antibodies of anti-NMDA receptor in the serum and/or CSF samples were defined according to previously reported criteria, including a characteristic pattern of immunostaining of neuropils in the rat brain and specific reactivity with HEK293 cells that express both the NR1 (also named GluN1) and NR2B (also named GluN2B) subunits of the NMDA receptor.

The clinical features were recorded by an experienced neurologist (J.Y, with more than 20 years of experience in neurology). According to the reported manifestations of this disease in previous publications, the symptoms were divided into 4 main groups: seizures; psychiatric and behavioral features; movement disorders, such as orolingual-facial dyskinesia and uncontrolled motion of the arms and legs; and other symptoms, such as memory deficits, autonomic symptoms (including salvation, urine and/or feces incontinence), central hypoventilation, hemiparesis, and abnormal heart rate. Additionally, the patients were classified into a pediatric group (younger than 18 years of age) or an adult group (18 years of age and older) depending on age.

Brain MR Imaging Acquisition

Brain MRIs were acquired at a mean time interval of 36 ± 15 days (range, 20–90 days) after the presentation onset using a Magnetom Tim Trio or Verio 3T scanner (Siemens, Erlangen, Germany) with an 8-channel phased array head coil in the Department of Radiology, Xuanwu Hospital, Capital Medical University. We obtained the following sequences: axial T2-weighted images (slice = 20, slice thickness = 5.0 mm, TR/TE = 4040/84 ms, flip angle = 160°, FOV = 240 mm), axial T1-weighted images (slice = 20, slice thickness = 5.0 mm, TR/TE = 135/2.55 ms, flip angle = 50°, FOV = 240 mm), coronal T1-weighted images (slice = 20, slice thickness = 5.0 mm, TR/TE = 162/3.09 ms, flip angle = 50°, FOV = 240 mm), and fluid-attenuated inversion recovery images (slice = 20, slice thickness = 5.0 mm, TR/TE = 8500/87 ms, flip angle = 150°, FOV = 230 mm). We defined abnormal brain MR imaging findings as hyperintensity on T2WI and FLAIR and hypointensity on T1WI; we classified abnormalities as hippocampal when hyperintensity or/and volume loss was found in the hippocampus.

Two experienced neuroradiologists (Y.L. and Y.D., both with >10 years of experience) assessed brain MR imaging manifestations, which were categorized into 4 types according to the previous reports after distinguishing constructed defects—type 1: normal MR imaging findings; type 2: only hippocampal lesions; type 3: lesions not involving the hippocampus; and type 4: lesions in both the hippocampus and other brain areas. Additionally, we measured medial temporal lobe atrophy (Y.L. and Y.D.) by visual assessment on both sides of the brain and used the following 2 categories: normal (MTA = 0–1) and abnormal (MTA ≥ 2). After 3 months, all the images were re-evaluated for MTA scores by the 2 raters. The interrater reproducibility was 98% and 96% at the 2 time points of evaluation; the intrarater reproducibility between the 2 raters was 96% and 94%, respectively.

Clinical Outcome Measurement

All 53 patients completed the 2-year follow-up. We used the modified Rankin Scale to define the clinical outcome (good [mRS = 0–1], recovered well and poor [mRS = 2–5, residual disability]) after immunotherapy treatment according to 2 experienced neurologists (J.Y. and W.X., one with more than 20 years of experience and one with 5 years of experience in neurology).

Statistical Analysis

Demographic variables including age (pediatric versus adult), sex, and clinical features were analyzed among the groups using the χ2 test. The relationship between baseline MR imaging characteristics and 2-year follow-up mRS scores was evaluated using partial correlation, with age, sex, and time interval (interval between the onset of presentation and MR imaging acquisition) as covariates. We assessed factors that may affect the prognosis by univariate and multivariate binary logistic regression (poor outcome defined as mRS = 2–5), using therapy method (surgery and immunotherapy), intensive care unit (ICU) admission, whether there was a relapse, and hippocampal involvement as factors and using age, sex, and time interval (interval between onset of presentation and MR imaging ac-
confirmed as ovarian teratomas.

Five female patients (9%, 4 adults and 1 child) had

In the final analysis, 53 patients with positive antibody titers and
definitively diagnosed with anti-NMDA receptor encephalitis

### RESULTS

#### Demographic and Clinical Characteristics

In the final analysis, 53 patients with positive antibody titers and
definitively diagnosed with anti-NMDA receptor encephalitis
were enrolled and completed the 2-year follow-up. For the anti-
body, the subtype of antibody and how the type of antibody im-

### Brain MR Imaging Features

Twenty-eight (28/53, 53%) patients with anti-NMDA receptor encephalitis
had normal MR imaging (type 1) results at the onset phase, and 25 patients (25/53; 47%) presented with abnormal MR imaging results—type 2: seven patients (7/25, 28%) with lesions in the hippocampus only; type 3: seven patients with lesions in the frontal lobe (n = 3); cingulate gyrus and middle cerebellar peduncle (n = 2); and corpus callosum, insula, basal ganglia, thalamus, andrain stem (n = 1), without hippocampal lesions; and type 4: 11

### Association between MR Imaging Characteristics and Clinical Outcome

The patients with hippocampal lesions had higher mRS scores
than those without hippocampal lesions after taking age, sex, and
time interval as covariates (P = .040 versus
P = .020). No

difference was observed in brain MR imaging manifestations be-
tween age groups (pediatric versus adult groups) (P = .982).

Forty-five patients had a normal MTA score (MTA = 0–1) on
both sides of the brain, 2 patients showed atrophy (MTA ≥ 2) on
both sides, and 6 patients showed atrophy in only 1 side: on the
right side in 2 patients (median MTA score = 2) and on the left
side in 4 patients (median MTA score = 2).

FIG 1. Four types of brain MR imaging appearances in patients with anti-NMDA receptor encephalitis, and the histogram of the 4 types of brain MR imaging appearance. Axial (A, C, and D) and coronal FLAIR images (B) come from 4 patients (C1 and C2 from same patient, D1 and D2 from same patient). A, Type 1, a 23-year-old male patient with anti-NMDA receptor encephalitis, with normal brain MR imaging findings. B, Type 2, a 29-year-old female patient. Lesions are in the left hippocampus with bilateral mild volume loss in the hippocampus. C, Type 3, a 28-year-old male patient. Lesions are in the right frontal lobe (white arrow) and middle cerebellar peduncle (white arrow) and brain stem. D, Type 4, a 25-year-old male patient, with lesions located in the bilateral frontal lobe, temporal lobe, insula (white arrows), hippocampus, and cingulate gyrus, with volume loss in the left hippocampus. E, Histogram of the 4 types of brain MR imaging appearances.

FIG 2. Lesion probability map of brain MR imaging. The mean lesion probability distribution thresholded at 34% is shown in light blue and thresholded at 1% is shown in blue and overlaid on the ICBM152 T1 template in the Montreal Neurological Institute space.
relapse ($P = .043$; OR = 0.111; 95% CI, 0.013–0.930). No correlation was observed between clinical outcome and intensive care unit admission, treatment, or teratoma (Table 2).

**DISCUSSION**

In this study, we demonstrated the MR imaging features of patients with Chinese anti-NMDA receptor encephalitis and their associations with clinical outcomes: 1) We categorized the brain MR imaging of anti-NMDA receptor encephalitis into 4 types and normal brain MR imaging acquisition findings accounted for >50% of cases. Normal brain MR imaging results were observed more frequently in female patients than in male patients. 2) Hippocampal lesions were the most common brain abnormality, and 3) hippocampal lesions and relapse were risk factors that contributed to a poor prognosis.

For demographic and clinical characteristics, the age distribution (range, 11–60 years; mean age, 26.4 years) in our study is similar to that in previous anti-NMDA receptor encephalitis studies, but the proportion of male patients is higher (47%) compared with previous studies. This divergence of sex differences between Chinese and Western patients may be due to racial differences or the relatively small sample size in our study. Therefore, future studies with larger samples are required to compare the demographic features between Chinese and Western patients. The clinical pattern and evolution are similar between adult and pediatric patients. For clinical symptoms, behavioral and psychiatric features were observed in the largest proportion of patients and are the main causes for admission to the hospital. Behavioral and psychiatric features and autonomic symptoms appeared in adults more frequently than in pediatric patients, which is consistent with previous research. Clinical relapse appeared in 10 patients (19%), which is similar to the 12%–24% frequency of neurologic relapse observed in previous studies.

Normal and abnormal brain MR imaging results were observed in 28 and 25 patients with the anti-NMDA receptor encephalitis, respectively; this finding is consistent with those in previous publications. In female patients, normal brain MR imaging findings were encountered more often than in male patients, implying the different lesion patterns between sexes. Further studies with advanced MR imaging techniques such as diffusion imaging and functional MR imaging should be conducted in the patients with normal routine brain MR imaging findings to reveal the microstructural and functional changes. In patients with abnormal brain MR imaging findings, lesions can occur in various locations such as the hippocampus, thalamus, basal ganglia, brain stem, insula, and frontal, temporal, and parietal lobes; and white matter lesions can occur in the corpus callosum, a finding reported by other studies. In the current study, to simplify the brain MR imaging patterns and characteristics, we classified brain MR imaging appearance into 4 types: type 1 (normal), type 2 (only hippocampal lesion), type 3 (lesions in other brain areas), and type 4 (hippocampal lesion and lesions in other areas). In these 3 abnormal types, type 4 was the most common pattern (21%), implying that lesions in other locations often occur together with hippocampal lesions in patients with anti-NMDA receptor encephalitis.

The hippocampus was the most common lesion site in patients with Chinese anti-NMDA receptor encephalitis, which was observed in approximately one-third of the patients. Previous studies have shown that structural hippocampal damage represented the target change in patients with anti-NMDA receptor encephalitis, which was significantly related to memory deficits and disease severity. Additionally, lesions located in the frontal and temporal lobes were present in approximately 15% of patients (21% and 15%), suggesting that the frontal and temporal lobes were the second most common lesion site after the hippocampus.

Medial temporal lobe atrophy as measured by MTA was observed in 8 patients (15%) on at least 1 side, indicating that structural damage in the hippocampus was relatively common. MTA of the left side was correlated with the mRS; this finding is consistent with that in a previous study showing that left hippocampal volume could predict disease severity. The findings suggest MTA as a valuable biomarker for predicting disease severity.

Poor prognosis was correlated with clinical relapse and hippocampal lesions in the present study, and hippocampal involvement had a stronger association with clinical outcome than relapse. Admission to an ICU, the method of treatment, and teratoma had no relationship with the clinical outcome. In several previous studies, some other factors were reported to be associated with clinical outcomes, including lack of a need for admission to an intensive care unit, low severity of the disease within 4 weeks, and a low titer of serum and CSF NMDA receptor antibodies, which were not identified in our study. The discordance between our study and some previous studies was due to the small number of patients, the different definitions of good prognosis, or the lack of an early mRS assessment.

**Limitations**

Our study has some limitations. First, the sample size was relatively small, and the significance and reliability of the results need to be improved by enrolling more subjects. Additionally, the data were obtained from a single center. Further studies should focus on multicenter samples to verify the results. Second, brain MR imaging was conducted only at the onset phase, so the MR imaging changes of this disease at different phases or changes with time could predict disease severity.

other auxiliary examinations are not clear. In this study, only routine sequences with slice thicknesses of 5 mm on brain MR imaging were obtained, on which it is difficult to detect small lesions and accurately measure the brain and hippocampal volumes. For MTA score assessment, only 79% of the patients had coronal images. A comprehensive scan and advanced MR imaging techniques with high resolution such as functional MR imaging should be conducted in these patients. Third, the assessment of clinical outcome in this study included only mRS scores at the 2-year follow-up. A more systematic assessment should be performed in a future study.

CONCLUSIONS
In patients with Chinese anti-NMDA receptor encephalitis, half had normal brain MR imaging findings, and normal brain MRI findings were more common in female patients. Psychiatric and behavioral abnormalities were more common in adults, and autonomic symptoms were more common in pediatric patients. Hippocampal lesions were the most common MR imaging abnormal finding. The presence of hippocampal lesions and relapse were major factors in the prediction of a poor prognosis.
