CT Texture Analysis of Cervical Lymph Nodes on Contrast-Enhanced [¹⁸F] FDG-PET/CT Images to Differentiate Nodal Metastases from Reactive Lymphadenopathy in HIV-Positive Patients with Head and Neck Squamous Cell Carcinoma

 H. Kuno,  N. Garg,  M.M. Qureshi,  M.N. Chapman,  B. Li,  S.K. Meibom,  M.T. Truong,  K. Takumi, and  O. Sakai

ABSTRACT

BACKGROUND AND PURPOSE: Differentiating nodal metastases from reactive adenopathy in HIV-infected patients with [¹⁸F] FDG-PET/CT can be challenging because lymph nodes in HIV-positive patients often show increased [¹⁸F] FDG uptake. The purpose of this study was to assess CT textural analysis characteristics of HIV-positive and HIV-negative lymph nodes on [¹⁸F] FDG-PET/CT to differentiate nodal metastases from disease-specific nodal reactivity.

MATERIALS AND METHODS: Nine HIV-positive patients with head and neck squamous cell carcinoma (7 men, 2 women; 29–62 years of age; median age, 48 years) with 22 lymph nodes (≥ 1 cm) who underwent contrast-enhanced CT with [¹⁸F] FDG-PET followed by pathologic evaluation of cervical lymph nodes were retrospectively reviewed. Twenty-six HIV-negative patients with head and neck squamous cell carcinoma with 61 lymph nodes were evaluated as a control group. Each lymph node was manually segmented, and an in-house-developed Matlab-based texture analysis program extracted 41 texture features from each segmented volume. A mixed linear regression model was used to compare the pathologically proved malignant lymph nodes with benign nodes in the 2 enrolled groups.

RESULTS: Thirteen (59%) lymph nodes in the HIV-positive group and 22 (36%) lymph nodes in the HIV-negative control group were confirmed as positive for metastases. There were 7 histogram features ($P = .017$ – 0.032), 3 gray-level co-occurrence features ($P = .009$ – $.025$), and 9 gray-level run-length features ($P < .001$ – $.033$) that demonstrated a significant difference in HIV-positive patients with either benign or malignant lymph nodes.

CONCLUSIONS: CT texture analysis may be useful as a noninvasive method of obtaining additional quantitative information to differentiate nodal metastases from disease-specific nodal reactivity in HIV-positive patients with head and neck squamous cell carcinoma.

ABBREVIATIONS: AUC = area under receiver operating characteristic curve; HNSCC = head and neck squamous cell carcinoma; GLCM = gray-level co-occurrence matrix; GLGM = gray-level gradient matrix; GLN = gray-level nonuniformity; GLRL = gray-level run-length; HGRE = high gray-level run emphasis; LGRE = low gray-level run emphasis; LRE = long-run emphasis; LRHGE = long-run high gray-level emphasis; max = maximum; RLN = run-length nonuniformity; RP = run percentage; SRE = short-run emphasis; SRLGE = short-run low gray-level emphasis; SUV = standard uptake value

Although patients with HIV have increased life expectancies through the introduction of highly active antiretroviral therapy,¹ there remains significant cancer-specific mortality in these

patients.^{2,3} Many of these patients are now acquiring malignancies that had previously not been associated with HIV or AIDS.^{4,5} The HIV-positive population is at an increased risk of head and neck squamous cell carcinoma (HNSCC) compared with the general population,^{6,7} and HNSCC is an increasingly common disease among individuals with HIV.⁸ HIV-positive HNSCCs have a more aggressive profile that leads to poorer patient outcomes,⁹ and HIV-positive patients have a concurrent increase in HNSCC-related mortality.^{3,4,10}

CT is the initial imaging technique for the diagnosis and staging of HNSCC below the hard palate at many institutions. However, HIV-positive patients often have diffuse bilateral lymph node enlargement consistent with AIDS-associated reactive adenopathy, cystic lesions, necrosis, or infections,^{11,12} and CT is sometimes limited for nodal staging. The introduction of [¹⁸F] FDG-PET/CT has enabled the metabolic assessment of lymph

• HIV-negative control group

FIG 1. Flowchart shows patient selection for the study.

nodes and is widely used for initially staging, restaging, and monitoring therapeutic responses for patients with head and neck squamous cell carcinoma.¹³⁻¹⁵ However, lymph nodes in HIV-positive patients often show increased [¹⁸F] FDG uptake, especially in the setting of high-plasma HIV RNA.¹⁶⁻¹⁸ Activated lymphocytes exhibit increased glucose use, and HIV-positive individuals have a greater accumulation of FDG in their lymph nodes than HIV-negative patients. Both HIV-1 and HNSCC can spread to the primary site of regional deep cervical lymph nodes,^{19,20} which makes metastatic determination and management complex.

There is increasing focus on using texture analysis to determine the features of CT images and elicit characteristics that may adequately describe nodal metastases despite the viral adenopathy.²¹⁻²³ Image texture analysis analyzes complex visual characteristics on the basis of underlying simpler patterns and then conducts quantitative comparisons of these characteristics between 2 images. Considering that these mathematic textural analyses have helped elucidate nuanced differences in pathology, we hypothesized that CT textural features would have the potential to add additional quantitative information in conjunction with [¹⁸F] FDG-PET/CT in HIV-positive HNSCC for the evaluation of lymph nodes. In addition, to the best of our knowledge, imaging studies including [¹⁸F] FDG-PET/CT of HIV-positive patients with head and neck squamous cell carcinoma related to lymph node adenopathy have not been fully explored in the literature. Hence, the purpose of this study was to assess the CT texture-analysis characteristics of HIV-positive and HIV-negative lymph nodes on [¹⁸F] FDG-PET/CT to differentiate nodal metastases from disease-specific nodal reactivity.

MATERIALS AND METHODS

Patients

The institutional review board approved this retrospective study. The requirement to obtain written informed consent was waived. The flowcharts of patient selection for HIV-positive patients and an HIV-negative control group in the study are shown in Fig 1.

HIV-Positive Patient Group

We retrospectively searched our electronic medical records to identify HIV-positive patients with untreated biopsy-proved HNSCCs who also underwent [¹⁸F] FDG-PET/CT before treatment between February 2009 and August 2015, and 20 patients were identified in total. Four of the 20 patients were excluded because they received nonsurgical treatment, such as chemoradiotherapy, without biopsy-proved pathologic confirmation of cervical lymph nodes. An additional 7 patients were excluded, 3 of whom were excluded due to non-contrast-enhanced [¹⁸F] FDG-PET/CT; and 4 patients, due to very small lymph nodes on CT (maximum size, <1 cm) that were difficult to analyze using the texture-analysis program. The remaining 9 patients (7 men, 2 women; 29–62 years of age; median age, 48 years; with 3 oral cavity, 3 oropharynx, 1 larynx, 1 maxillary sinus, and 1 primary unknown lesion) with 22 lymph nodes (maximum size, ≥1 cm) were enrolled in this study.

The electronic medical records were reviewed on all subjects, specifically for the presence of pathologically confirmed cervical lymph node metastasis at first treatment with neck dissection. The dates of the first surgical procedure and patient outcomes such as the presence of metastatic recurrence in a cervical lymph node within 1 year after surgery were also noted.

HIV-Negative Patient Group for Controls

We also identified HIV-negative patients with untreated biopsy-proved HNSCCs as a control group to investigate how HIV infection affects the texture features and standard uptake values (SUVs) of the nodal metastasis and reactive adenopathy. Between December 2009 and December 2013, one hundred thirty-eight consecutive HIV-negative patients with newly diagnosed primary head and neck squamous cell carcinoma underwent [¹⁸F] FDG-PET/CT before treatment. Fifty-three of the 138 patients were excluded because they received nonsurgical treatment without pathologic confirmation of cervical lymph nodes. An additional 25 patients were excluded because only non-contrast-enhanced [¹⁸F] FDG-PET/CT was performed. In addition, 34 patients with

small lymph nodes on CT (maximum size, <1 cm) were also excluded. The remaining 26 patients (17 men, 9 women; 30–86 years of age; median age, 59 years; with 12 oral cavity, 10 oropharynx, 1 hypopharynx, and 3 larynx lesions) with 61 lymph nodes (node size, ≥ 1 cm) were enrolled in this study as a control group.

PET/CT Imaging Protocol

For image analysis, the pretreatment PET/CT was used to obtain CT texture analysis and FDG uptake. All [^{18}F] FDG-PET/CT studies were performed on an integrated PET/CT scanner combining PET with a 16-slice multidetector row CT (Discovery STE 16; GE Healthcare, Milwaukee, Wisconsin). Patients were injected with an average of 10.59 mCi of [^{18}F] FDG, and it was incubated for an average of 62 minutes. The amount of injected radioactivity was routinely measured by quantification of the radioactivity of the syringe before and after injection. Patients were scanned in a supine position from the skull base to midthigh on a flat table with a head and neck acquisition separate from the body acquisition. All patients were scanned using a dedicated head and neck protocol.

The dedicated head and neck CT studies were helically acquired (120 kV[peak], gantry rotation time = 0.5 seconds, kVp = 120, auto milliamperage, minimum = 299 mA, maximum = 440 mA, noise index = 11, helical pitch factor = 0.937:1, scan FOV = 30 cm, reconstructed slice thickness = 1.25 mm, image matrix = 512×512) extending from the skull base to thoracic inlet following a 60-second delay after intravenous contrast injection (60 mL of ioversol, Optiray 350, Mallinckrodt, St. Louis, Missouri; or iopamidol, Isovue 370, Bracco, Princeton, New Jersey). The images were reviewed in soft-tissue algorithms. The dedicated head and neck PET scans were obtained using 2D imaging with emission scans lasting between 5 and 6 minutes, and an FOV of 30 cm. The matrix size was 128×128 , and slice thickness was 3.3 mm.

Image Segmentation and Texture Analysis on CT

Multiple lymph nodes (up to 5 per patient, selected on the basis of a maximum size of >1 cm) were analyzed for CT texture analysis and FDG uptake. Each lymph node was manually contoured by a neuroradiologist with 10 years of experience. Segmentation of the lymph nodes was performed using OsiriX Imaging Software (<http://www.osirix-viewer.com>). The entire lymph node, including necrotic or cystic areas, was segmented for analysis. For a subanalysis, ROIs without obvious necrotic or cystic areas were also created (On-line Figure). When severe streak artifacts within the lymph node were seen, the slices with severe artifacts were excluded and only artifact-free slices were used for texture analysis. Each contoured image was imported into an in-house-developed Matlab-based (MathWorks, Natick, Massachusetts) texture analysis software.^{24,25} We discuss the extraneous math behind each texture feature in detail in a subsequent On-line Appendix.^{24,26–31} In total, 41 texture features, including 12 histogram features, 5 gray-level co-occurrence matrix (GLCM) features, 11 gray-level run-length (GLRL) features, 4 gray-level gradient matrix (GLGM) features, and 9 Laws features, were computed and averaged over the images per dataset. The mean value of the textural features was estimated. Both the volume and size of each lymph node were also calculated.

[^{18}F] FDG-PET/CT Image Analysis

The PET study and contrast-enhanced CT scan were viewed independently and as coregistered studies using a Vista workstation (MIM Software, Cleveland, Ohio). PET, CT, and fused PET/CT images were reviewed in the axial planes. Standard uptake value maximum (SUVmax), the maximum SUV within the tumor normalized to lean body mass from PET, was measured by drawing an ROI slightly outside each lesion corresponding to those used for texture analysis on the CT image for each patient.

Statistical Analysis

We compared the 41 texture parameters, SUVmax, lymph node size, and volume: 1) the malignant nodes with benign nodes in the HIV-positive group (group 2 versus 1); 2) the malignant lymph nodes with benign nodes in the HIV-negative group (group 4 versus 3); 3) the benign lymph nodes in the HIV-positive group with benign lymph nodes in the HIV-negative group (group 1 versus 3); and 4) the malignant lymph nodes in the HIV-positive group with malignant lymph nodes in the HIV-negative group (group 2 versus 4). For each group comparison, we used the mixed linear regression model (Proc MIXED; http://support.sas.com/documentation/cdl/en/statug/63033/HTML/default/viewer.htm#mixed_toc.htm) to take into consideration data clustering using the SAS 9.3 system (SAS Institute, Cary, North Carolina). Because each patient could contribute >1 lymph node, this approach allowed modeling of the variance-covariance matrix among multiple values recorded for each patient. Compound symmetry was specified for the covariance structure. To assess the potential clinical utility of texture features and nodal characteristics, we constructed receiver operating characteristic curves for repeat-measures designs to determine the performance and optimal cutoff point of each parameter in distinguishing the 2 node characterizations (for example, benign versus malignant lymph nodes in HIV-positive patients).³² The point on the receiver operating characteristic curve farthest from the 45-degree reference line with the best combination of sensitivity and specificity was considered the optimum cutoff point. The area under the receiver operating characteristic curve (AUC) was used to assess the predicted validity of each parameter. The closer the AUC value is to 1.0, the more predictive the features are with respect to malignant lymph nodes. Associations of demographic and clinical characteristics with HIV-positive and HIV-negative groups were tested with the Pearson χ^2 test or the Mann-Whitney U test. Due to the relatively small sample size and exploratory nature of this study, correction for multiple comparisons was not applied, and an uncorrected P value of .05 was regarded as the statistical threshold of significance for all analyses.

RESULTS

For HIV-positive patients, the median absolute CD4 counts were 473 cells/mm³ (range, 172–1809 cells/mm³), and 8 of 9 patients were receiving highly active antiretroviral therapy. In the HIV-positive group, 13 (59%) lymph nodes in 6 patients were confirmed as malignant (positive for metastases), and 9 (41%) lymph nodes in 5 patients were confirmed as benign (negative for metastases). Two patients in the HIV-positive group had both malignant and benign nodes. In the HIV-negative control group, 22 (36%) lymph nodes in 13 patients were confirmed as malignant (positive for metastases), and 39 (66%) lymph nodes in 20 pa-

tients were confirmed as benign (negative for metastases). Ten patients in the HIV-negative group had both malignant and benign nodes. Complete patient demographics and tumor characteristics are described in Table 1. The primary site and T-stage were not significantly different between the HIV-positive and HIV-negative groups.

Analysis between Lymph Node Characterization in HIV-Positive and HIV-Negative Patients with HNSCC

HIV-Positive Patient Group. The results of the [¹⁸F] FDG-PET/CT characteristics (SUVmax, node size, and node volume) and the 41 texture parameters differentiating lymph node characterization in HIV-positive patients with head and neck squamous cell carcinoma (group 1 versus 2) are shown in Table 2 (for selected parameters) and On-line Table 1 (for 41 parameters). There was a significant difference in the SUVmax (5.11 for benign nodes versus 8.56 for malignant nodes, $P = .042$), node size (1.40 cm for benign nodes versus 1.89 cm for malignant nodes, $P = .024$), and node volume (0.55 cm³ for benign nodes versus 2.54 cm³ for malignant nodes, $P = .007$) between malignant and benign nodes for the HIV-positive group. For the CT texture analysis in the HIV-positive group, there were 7 histogram features, including mean ($P = .017$), median ($P = .018$), second SD ($P = .017$), range ($P = .017$), geometric mean ($P = .032$), SD 5 ($P = .018$), and SD 9 ($P = .017$); 3 GLCM features, including contrast ($P = .009$), energy ($P = .025$), and homogeneity ($P = .020$); and 9 GLRL features, including short-run emphasis (SRE) ($P < .001$), long-run emphasis (LRE) ($P = .001$), gray-level nonuniformity (GLN) ($P = .001$), run-length nonuniformity (RLN) ($P = .002$), run percentage (RP) ($P = .033$), low gray-level run emphasis

(LGRE) ($P = .013$), high gray-level run emphasis (HGRE) ($P = .008$), short-run low gray-level emphasis (SRLGE) ($P = .021$), and long-run high gray-level emphasis (LRHGE) ($P = .035$) that demonstrated a significant difference in HIV-positive patients with either benign or malignant lymph nodes (On-line Table 1). No statistically significant differences were seen in the GLGM and Laws texture features. Among the imaging characteristics, the highest AUC to predict a malignant lymph node was 0.89, with a sensitivity of 92.3% and a specificity of 77.8% in node volume. Among the 41 texture features, the highest AUC was 0.97, with a sensitivity of 84.6% and a specificity of 100% in SRE, which is categorized as a GLRL feature (Table 2).

For the HIV-positive group, the optimal SUV cutoff was 5.50 for benign-versus-malignant nodes, and 3.98 for the HIV negative group (Tables 2 and 3). Among the 13 malignant nodes, 11 (84.6%) were correctly detected by both SUV and texture analysis (SRE); however, 2 (15.4%) false-negative findings were observed even using SUV and texture analysis (SRE). Among the 9 benign nodes, 2 (22.2%) were observed as false-positive findings on the SUV cutoff point (SUVmax = 8.1 and 7.4), whereas no false-positive findings were observed on texture analysis (SRE). Figure 2 shows a representative case of a false-positive finding on FDG-PET for benign nodes in an HIV-positive patient with HNSCC who had both benign and malignant nodes.

HIV-Negative Patient Subgroup as Controls. The results of the [¹⁸F] FDG-PET/CT characteristics (SUVmax, node size, and node volume) and the 41 texture parameters differentiating lymph node characterization in HIV-negative patients with head and neck squamous cell carcinoma (group 3 versus 4) are shown in Table 3 (for selected parameters) and On-line Table 2 (for 41 parameters). The node volume for the HIV-negative group (1.12 mL for benign nodes versus 3.47 mL for malignant nodes, $P = .001$) and the SUVmax for the HIV-negative group (3.23 for benign nodes versus 6.44 for malignant nodes, $P = .007$) showed significant differences. For the CT texture analysis, statistically significant differences among lymph node characterizations in patients with head and neck squamous cell carcinoma were seen in 5 histogram features, including mean ($P = .022$), geometric mean ($P = .020$), harmonic mean ($P = .020$), interquartile range ($P = .022$), and fourth moment ($P = .018$); 3 GLCM features, including contrast ($P = .015$), energy ($P = .034$), and homogeneity ($P = .029$); 5 GLRL features, including SRE ($P = .036$), RLN ($P = .034$), short-run high gray-level emphasis ($P = .016$), long-run low gray-level emphasis ($P = .006$), and LRHGE ($P = .003$); and 9 Laws features ($P = .024$ –.047), while there was no statistically significant difference in GLGM. The highest AUC among the 41 texture features to predict a malignant lymph node was 0.76 with the texture parameter of LRHGE (sensitivity of 54.6% and specificity of 84.6%), whereas the highest AUC among the imaging characteristics was SUVmax (AUC = 0.73, sensitivity = 63.6%, and specificity = 79.5%) (Table 3).

FIG 2. Representative case of false-positive findings on FDG-PET for benign nodes in a 74-year-old woman with unknown primary squamous cell carcinoma who had both benign and malignant nodes (HIV-positive; absolute CD4 = 473). Axial contrast-enhanced CT images (A and D), [^{18}F] FDG-PET/CT fusion images (B and E), and corresponding axial section ROI mask-segmented lymph nodes (C and F) for pathologically benign (A–C) and malignant (D–F) lymph nodes. [^{18}F] FDG-PET/CT shows abnormal uptake (cutoff = >5.5) for both lymph nodes with SUVmax = 8.1 (benign, B) and 9.5 (malignant, E). However, texture features with SRE (cutoff = <0.164) of both lymph nodes were correctly diagnosed as follows: 0.188 (benign, C) and 0.151 (malignant, F).

patients with head and neck squamous cell carcinoma with benign nodes (group 1 versus 3) are shown in On-line Table 3. For benign lymph nodes, the point estimate of the SUVmax of HIV-positive (5.11) was higher than that of HIV-negative (3.23); however, the difference among the SUVmax of HIV statuses was not statistically significant ($P = .111$). No statistically significant differences were seen in the node size (1.40 cm for HIV-positive versus 1.44 cm for HIV-negative, $P = .781$) and node volume (0.58 cm^3 for HIV-positive versus 1.12 cm^3 , $P = .137$) between the HIV-positive and HIV-negative groups. For the CT texture analysis in benign lymph nodes, there were 5 GLRL features, SRE ($P = .017$), LRE ($P = .027$), GLN ($P = .021$), LGRE ($P = .044$), and HGRE ($P = .012$), that demonstrated a significant difference with HIV-positive and HIV-negative patients. No statistically significant differences were seen in the histogram, GLCM, GLGM, and Laws texture features. Among the imaging characteristics and the 41 texture features, the highest AUC to predict HIV-infected lymph nodes was 0.87, with a sensitivity of 100% and a specificity of 84.6% in SUVmax.

Malignant Lymph Node (Positive for Metastases) Subgroup. The results of the texture parameters differentiating HIV infections in patients with head and neck squamous cell carcinoma with malignant nodes (group 2 versus 4) are shown in On-line Table 4. For malignant lymph nodes, there was no statistically significant differences in the SUVmax (8.56 for HIV-positive versus 6.46 for HIV-negative, $P = .192$), node size (1.89 cm for HIV-positive versus 1.69 cm for HIV-negative, $P = .186$), and node volume (2.54 cm^3 for HIV-positive versus 3.47 cm^3 , $P = .409$) between the HIV-positive and HIV-negative groups. Of the 41 CT texture analysis parameters in malignant lymph nodes, there were no statistically significant differences in the histogram, GLCM, GLGM, GLRL, and Laws texture features.

Subanalysis of Texture Features of Lymph Nodes without and with Exclusion of Necrotic Areas Differentiating Benign-versus-Malignant Lymph Nodes

The results of subanalysis of the lymph node characterization without and with exclusion of areas of obvious necrosis or cystic parts are shown in On-line Table 5 for patients with HIV (group 1 versus 2) and in On-line Table 6 for patients without HIV (group 3 versus 4). Even excluding the obvious necrotic parts, there was no major change in which a parameter was effective in distinguishing benign and malignant nodes. For the patients with HIV (group 1 versus 2), there were 6 histogram features ($P = .034$ – $.045$), 3 GLCM features ($P = .031$ – $.045$), and 4 GLRL features ($P = .011$ – $.048$) that demonstrated a significant difference in HIV-positive patients with either benign or malignant lymph nodes. For the patients without HIV (group 3 versus 4), there were 3 histogram features ($P = .032$ – $.043$), 2 GLCM features

($P = .037$ – $.047$), and 3 GLRL features ($P < .001$ – $.01$) that demonstrated a significant difference in HIV-positive patients with either benign or malignant lymph nodes. However, the AUC of the analysis, including the necrotic parts, was higher than that of the subanalysis excluding the necrotic parts for all texture parameters.

DISCUSSION

The results of our study demonstrated that the histogram, GLCM, and GLRL CT texture parameters of the lymph nodes showed a significant difference between metastatic lymph nodes and HIV-related lymphadenopathy in patients with head and neck squamous cell carcinoma with HIV infection. CT texture features, especially space-dependent features such as GLCM and GLRL, may provide important additional information to differentiate nodal metastases from disease-specific nodal reactivity in HIV-positive patients with head and neck squamous cell carcinoma.

In our study, none of the CT textural analysis features were found to have statistically significant differences between HIV-positive and HIV-negative patients with malignant lymph nodes. The lack of a significant difference suggests almost similar texture for HNSCC metastatic nodes regardless of HIV infection status. On the other hand, benign lymph nodes showed different textures in 5 GLRL features between HIV-positive and HIV-negative lymph nodes. HIV-positive patients often have lymph node enlargement consistent with AIDS-associated reactive adenopathy, and HIV viral loads may also be associated with viral infection, including human papillomavirus and Epstein-Barr virus, which are well-known etiologies of HNSCC.^{6,8} Therefore, the texture features may potentially reflect a different degree of uniformity due to inflammation or viral infection within the lymph nodes along both long and short matrix runs. Space-dependent texture

features such as GLRL on CT images could demonstrate significant differences in benign lymph nodes in HIV-positive patients with head and neck squamous cell carcinoma, which may have the potential to prove morphologic feature differences among disease-specific nodal reactivity in HIV-positive patients with head and neck squamous cell carcinoma.

CT texture analysis is a postprocessing technique and a new addition to the image-analysis armamentarium that extracts information native to image data that is not apparent on visual inspection of images. CT texture analysis has started to be investigated for its ability to predict lymph node metastasis in patients with lung cancer.^{21,33} In our study, for assessment of metastatic lymph nodes in HIV-negative patients, some histogram and GLRL texture features may be associated with nodal metastasis in patients with head and neck squamous cell carcinoma. However, the predictions of malignant nodes using texture analysis were almost similar to SUV values in HIV-negative patients. Further testing using a larger sample size is needed to validate the performance of the predictive model.

Immunosuppression predisposes HIV-infected patients to a number of opportunistic infections; therefore, special care must be taken in evaluating [¹⁸F] FDG-PET/CT. Benign hypermetabolic foci are common, especially in the context of high levels of HIV viremia (low CD4 counts) and can lead to false-positive interpretations of metastasis using only the SUV cutoff point.^{16,18,34} In past years, other quantitative approaches, including metabolic tumor volume and total lesion glycolysis for [¹⁸F] FDG-PET evaluations, have been investigated for differentiation of HIV-associated lymphoma from HIV-associated reactive adenopathy.^{35,36} CT texture features can also be obtained from the same [¹⁸F] FDG-PET/CT study. The combination model based on these quantitative PET metabolic metrics, CT texture parameters, and clinical parameters may need to be further evaluated in a future study for patients with head and neck squamous cell carcinoma.

There are several limitations associated with the small sample size in this study. This study included only a small number of HIV-infected patients with head and neck squamous cell carcinoma, and there were imbalances among the different groups. The statistical analysis was potentially limited in that the more reasonable analyses, including multiple-comparison correction, could not be conducted. The small sample size could also potentially mask the weak differences. In addition, for the HIV-positive group, there is a wide range of absolute CD4 cell counts, and a subset of patients were receiving highly active antiretroviral therapy. These distributions have significant implications for mounting an immune reaction and therefore potentially for the texture features of lymph nodes. Therefore, detailed analyses using stratification based on CD4 counts and administration of therapeutic regimens considering the influence of the status of HIV are desirable. These problems could be solved in future studies with larger sample sizes.

CONCLUSIONS

Histogram, GLCM, and GLRL CT texture parameters of the lymph nodes are associated with nodal metastasis in patients with head and neck squamous cell carcinoma with HIV infection. Although further testing using a larger sample size is needed to val-

idate the performance, CT texture analysis may be useful as a noninvasive method for obtaining additional quantitative information to differentiate nodal metastases from disease-specific nodal reactivity in HIV-positive patients with head and neck squamous cell carcinoma.
