CT Scanning in Suspected Stroke or Head Trauma: Is it Worth to go the Extra Mile and Include the Chest to Screen for COVID-19 Infection?

R.M. Kwee, J. Krdzalic, B.A.C.M. Fasen, and T.M.H. de Jaegere, for the COVID-19 CT Investigators South-East Netherlands (CISEN) Study Group

ABSTRACT

BACKGROUND AND PURPOSE: Chest CT may be used as a tool for rapid coronavirus disease 2019 (COVID-19) detection. Our aim was to investigate the value of additional chest CT for detection of coronavirus 19 (COVID-19) in patients who undergo head CT for suspected stroke or head trauma in a COVID-19-endemic region.

MATERIALS AND METHODS: Our study included 27 patients (mean age, 74 years; range, 54–90 years; 20 men) who underwent head CT for suspected stroke (n = 21) or head trauma (n = 6), additional chest CT for COVID-19 detection, and real-time reverse transcriptase polymerase chain reaction testing in a COVID-19-endemic region. Sensitivity, specificity, and negative and positive predictive values of chest CT in detecting COVID-19 were calculated.

RESULTS: Final neurologic diagnoses were ischemic stroke (n = 11), brain contusion (n = 5), nontraumatic intracranial hemorrhage (n = 2), brain metastasis (n = 1), and no primary neurologic disorder (n = 8). Symptoms of possible COVID-19 infection (ie, fever, cough, and/or shortness of breath) were present in 20 of 27 (74%) patients. Seven of 27 patients (26%) had real-time reverse transcriptase polymerase chain reaction confirmed–COVID-19 infection. Chest CT results were 6 true-positives, 15 true-negatives, 5 false-positives, and 1 false-negative. Diagnostic performance values of chest CT were a sensitivity of 85.7%, specificity of 75.0%, negative predictive value of 93.8%, and positive predictive value of 54.6%.

CONCLUSIONS: The sensitivity of additional chest CT is fairly high. However, a negative result does not exclude COVID-19. The positive predictive value is poor. Correlation of chest CT results with epidemiologic history and clinical presentation, along with real-time reverse transcriptase polymerase chain reaction, is needed for confirmation.

ABBREVIATIONS: COVID-19 = coronavirus disease 2019; RT-PCR = real-time reverse transcriptase polymerase chain reaction

The coronavirus disease 2019 (COVID-19) pandemic has caused a global crisis. As of April 19, there were 2,356,475 confirmed cases and 162,070 deaths worldwide.1 In regions where COVID-19 is highly endemic, some hospitals can barely handle the influx of patients.2–4 Nevertheless, rapid triage and isolation of patients with suspected COVID-19 are essential to prevent hospital-related transmission of the virus to other patients and health care workers.5,6 Stroke and traumatic brain injury are highly prevalent worldwide7 and remain common reasons for emergency department visits.8 These patients should be assessed for COVID-19 infection on emergency department arrival in COVID-19-endemic areas. One possible strategy is to perform real-time reverse transcriptase polymerase chain reaction (RT-PCR) in patients who are being hospitalized. However, a major disadvantage of RT-PCR testing is that it takes several hours to obtain results. It has been suggested that chest CT may be used as a tool for rapid COVID-19 detection in endemic areas.9 Head CT is the primary imaging technique of choice to evaluate patients with suspected stroke10,11 or head trauma12 in the emergency setting. Thus, it may be possible to perform additional chest CT for COVID-19 detection in 1 session with head CT. This approach could be particularly useful when rapid triaging is needed and RT-PCR testing capacity and the number of isolation rooms are limited. Furthermore, such a strategy poses a negligible extra burden on available CT equipment and radiology personnel. In addition, the additional radiation exposure of chest CT is not a major concern because patients with suspected stroke or head trauma are usually older and chest CT can be performed with a low-dose protocol.13 Therefore, the purpose of our study was to investigate...
the value of additional chest CT for COVID-19 detection in patients who undergo head CT for suspected stroke or head trauma in a COVID-19-endemic region.

MATERIALS AND METHODS

Patients

This retrospective study was approved by the institutional review board of our hospital (Zuyderland Medical Center, Heerlen/Sittard/Gleen, the Netherlands) (No. Z2020061), and patient consent was waived. We included 27 consecutive patients (mean age, 74 years; range, 54–90 years; 20 men) who were evaluated for suspected stroke (n = 21) or head trauma (n = 6) in our hospital between March 12, 2020, and April 14, 2020. Our hospital, one of the largest general hospitals in the Netherlands, was located in a COVID-19-endemic region. Our study period encompassed the peak of the highest registered number of daily COVID-19 infections in the Netherlands.14 During the study period, patients had to be transported to other hospitals because the intensive care unit of our hospital was becoming overloaded (as of April 1, 2020, eighty-three percent of all intensive care unit beds were occupied by patients with COVID-19). All 27 patients underwent head CT, additional chest CT for COVID-19 detection, and RT-PCR testing of nasopharyngeal and oropharyngeal swabs. In 3 patients with suspected stroke, CTA was also performed from the aortic arch to the vertex to evaluate for intracranial large-vessel occlusion.

Chest CT Protocol

Chest CT was performed on either a 64-section CT scanner (Inisive; Philips Healthcare) or on a 64-section dual-source scanner (Somatom Definition Flash; Siemens). Scanning parameters were the following: collimation = 64 × 0.625 or 0.6 mm, Tube voltage = 120 kV(peak), Tube current = 667 maximum mA or 404 maximum mA, pitch = 1.0 or 1.2, and matrix size 5 = 12 × 512. CT images were reconstructed with a lung kernel in the transverse plane with a 1.0-mm section thickness and a 1.0-mm increment. Images were also reconstructed in axial, coronal, and sagittal planes with a 3.0-mm section thickness.

RESULTS

Patients

Final neurologic diagnoses were ischemic stroke (n = 11), brain contusion (n = 5), nontraumatic intracranial hemorrhage (n = 2), brain metastasis (n = 1), and no primary neurologic disorder (n = 8). Correlation of symptoms of possible COVID-19 infection (ie, fever, cough, and/or shortness of breath16), chest CT findings, and RT-PCR results are shown in Table 2. Symptoms of possible COVID-19 infection were present in 20 of 27 (74%)
patients. The median time interval between CT and RT-PCR was 0 days (range, 0–7 days; interquartile range, 0–1 day). In 2 of 4 patients with a chest CT result positive for COVID-19 but negative findings on the initial RT-PCR, repeat RT-PCR was performed (with findings remaining negative). Seven of 27 patients (26%) had RT-PCR–confirmed COVID-19 infection. Six patients with RT-PCR–confirmed COVID-19 were symptomatic, whereas 1 patient with RT-PCR–confirmed COVID-19 was asymptomatic. In the asymptomatic patient with RT-PCR–confirmed COVID-19, abnormalities suspicious for COVID-19 were already visible in the upper lung fields on CTA, which was confirmed on additional chest CT (Fig 1). In another patient with head trauma and fever, chest CT findings were negative, whereas RT-PCR 4 days after CT showed COVID-19. This patient was not isolated until the RT-PCR results were known.

### Diagnostic Yield of Chest CT

Typical, indeterminate, atypical, and negative chest CT features for COVID-19 were present in 3, 8, 2, and 14 patients, respectively. Figs 1 and 2 show examples of typical chest CT features of COVID-19, whereas Fig 3 shows an example of atypical chest CT features of COVID-19. Chest CT results were 6 true-positives, 15 true-negatives, 5 false-positives, and 1 false-negative. Diagnostic performance values of chest CT were a sensitivity of 85.7%, specificity of 75.0%, negative predictive value of 93.8%, and positive predictive value of 54.6%.

### DISCUSSION

Our initial experience in 27 patients with an emergency indication for head CT shows that the sensitivity of additional chest CT for COVID-19 is fairly high. An estimated 5%–80% of COVID-19-infected persons may be asymptomatic. Although asymptomatic, they may transmit the disease to others. In our study, 7 of 27 patients (26%) did not have symptoms of possible COVID-19 infection (ie, fever, cough, and/or shortness of breath). One of these asymptomatic patients proved to be infected with COVID-19 by RT-PCR. This finding underlines the importance of vigilantly evaluating the lungs on CTA scans of patients with stroke in a COVID-19-endemic region, even when they are asymptomatic. However, a negative result does not exclude COVID-19. In 1 patient with head trauma and fever, chest CT had negative findings, whereas RT-PCR 4 days after CT showed COVID-19 infection. This patient was not isolated until the RT-PCR results were known and could have put other patients and health care workers at risk to become infected too. Furthermore, the positive predictive value of chest CT was poor. If only chest CT results were used to make patient-management decisions, too many cases would unnecessarily occupy isolation rooms. Therefore, correlation with epidemiologic history and clinical presentation, along with the RT-PCR, is needed for confirmation.

The diagnostic accuracy of chest CT has been investigated by a few previous studies, in different populations. Our study is unique in that it investigated the value of additional chest CT in patients who already underwent head CT in a COVID-19-endemic region, compared with

features were interpreted as atypical for COVID-19 pneumonia. RT-PCR was negative for COVID-19. Most important, our observation that a negative chest CT result does not exclude COVID-19 is supported by a study among passengers from the cruise ship Diamond Princess, which showed that 6 of 28 symptomatic patients with COVID-19 had normal chest CT findings.25

RT-PCR of nasopharyngeal and oropharyngeal specimens is considered the standard to diagnose COVID-19.26–29 However, currently available RT-PCR tests are time-consuming (it takes several hours before the results are known), and there is still relatively limited RT-PCR testing capacity worldwide.30,31 In a heavily constrained environment with a lack of sufficient RT-PCR testing capacity and a shortage of isolation beds, additional chest CT may be performed to detect COVID-19 in patients who have already undergone head CT. The data from this study may be used to weigh the potential advantages and disadvantages of performing additional chest CT in such settings. On a different note, additional chest CT in patients who require CT scanning of other body regions may also be helpful for taking appropriate actions in a timely manner to maintain the safety of the CT room. If chest CT findings are positive for possible COVID-19, the CT room should be decontaminated (room downtime for decontamination is typically between 30 minutes to 1 hour) before scanning the next patient.

Our study has some limitations. First, the number of included patients was relatively low. Nevertheless, we were able to demonstrate the value of additional chest CT for COVID-19 detection in patients with suspected stroke or head trauma. Second, in previous studies that reported chest CT as a stand-alone method in patients who may otherwise not have undergone CT scanning,9,23,24 furthermore, our study also included asymptomatic patients (26% of our study population) with respect to possible COVID-19. Because of the inclusion of patients without any COVID-19 symptoms, the overall prevalence of COVID-19 infection in our study population was lower than that in previous studies9,23,24 (26% in our study versus 39%–85% in previous studies9,23,24). Nevertheless, the fairly high sensitivity and poor specificity of additional chest CT is in line with the findings of previous studies that reported sensitivity and specificity values of 93.2%–97.0%, and 25.0%–53.3%, respectively.9,23,24 Most important, our observation that a negative chest CT result does not exclude COVID-19 is supported by a study among passengers from the cruise ship Diamond Princess, which showed that 6 of 28 symptomatic patients with COVID-19 had normal chest CT findings.25

RT-PCR of nasopharyngeal and oropharyngeal specimens is considered the standard to diagnose COVID-19.26–29 However, currently available RT-PCR tests are time-consuming (it takes several hours before the results are known), and there is still relatively limited RT-PCR testing capacity worldwide.30,31 In a heavily constrained environment with a lack of sufficient RT-PCR testing capacity and a shortage of isolation beds, additional chest CT may be performed to detect COVID-19 in patients who have already undergone head CT.
