Isolated Posterior Cerebral Artery Dissection: Report of Three Cases

SUMMARY: Isolated dissection of the posterior cerebral artery (PCA) is a rare but important cause of stroke in younger patients, particularly women. We present 3 cases of dissection of the P2 segment of the PCA. In 2 patients, an association with minor axial head trauma was documented, suggesting shearing injury of the PCA as it crosses over the free edge of the tentorium. The clinical and imaging findings are discussed, and the therapeutic management is reviewed.

CASE REPORT

P. Sherman

P. Gailloud

Extracranial and intracranial arterial dissection is an important cause of stroke in younger patients. Intracranial arterial dissections most often involve the vertebrobasilar system and, less commonly, the middle and anterior cerebral arteries. Isolated dissection of the posterior cerebral artery (PCA) is rare, but accurate diagnosis is important for appropriate clinical management. We present 3 cases of dissection of the P2 segment of the PCA, 2 of which occurred in association with minor head trauma.

Case Reports

Case 1

A 47-year-old woman with medically controlled arterial hypertension presented to the emergency department with occipital headache and acute left lower quadruparesis. She reported a 45-minute episode of left lower face and left-handed tingling that occurred 2 days before admission and resolved spontaneously. Additional history was significant for mild head trauma approximately 1 week before, when she had experienced a few minutes of dizziness after banging the top of her head on a wooden table. The general and neurologic examination at the time of presentation was unremarkable. In particular, the visual fields were full to confrontation. Findings of noncontrast brain CT were unremarkable. MR imaging demonstrated fluid-attenuated inversion recovery (FLAIR) hyperintensity (Fig 1A) with associated restricted diffusion (Fig 2A) and to a lesser extent in the right occipital lobe, compatible with subacute infarcts.

MR angiography demonstrated focal absence of flow-related enhancement in the P2 segment of the right PCA, which was attributed to slow or absent flow. Findings of transesophageal echocardiography and bilateral carotid duplex sonography were unremarkable, as were the results of the screening for hypercoagulability disorders. The patient was started on enoxaparin (Lovenox) and warfarin (Coumadin) with a target international normalized ratio between 2.0 and 3.0. Lovenox was discontinued when the patient was at therapeutic levels on Coumadin. At the time of discharge, the visual field deficit had resolved. Follow-up CT angiography performed 6 months later demonstrated an improved, but still present, irregularity and narrowing of the P2 segment of the right PCA. The patient was asymptomatic, and findings of the neurologic examination were normal. The decision was made to continue anticoagulation and perform further follow-up imaging 6 months later. DSA, performed at 1 year, demonstrated a mild persistent irregular contour of the PCA as well as a flow in a second lumen parallel to the PCA, consistent with recanalization of a focal arterial dissection ("double lumen" sign) (Fig 1D). D3D DSA clarified the complex morphology of the true and false lumen of the right PCA, immediately distal to the posterior communicating artery (Fig 1E).

Case 2

A 7-year-old girl with a history of attention deficit disorder and microcephaly presented to the emergency department with a 3-day history of left hemiparesis that appeared shortly after her older sister had accidentally dropped the edge of a mattress on the top of her head. There was no loss of consciousness. Head CT obtained 4 days after the onset of symptoms demonstrated an area of hypodensity in the right thalamus and basal ganglia. MR imaging demonstrated FLAIR hyperintensity in the right thalamus and posterior limb of the internal capsule (Fig 2A), associated with restricted diffusion (Fig 2B) and mild enhancement. MR angiography showed narrowing of the proximal right PCA. Findings of echocardiography, hypercoagulability screening, and autoimmune disease evaluation were negative. Cerebral DSA demonstrated a focal narrowing of the proximal P2 segment of the right PCA, distal to the posterior communicating artery termination (Fig 2C), with a slightly beaded appearance. During the capsular phase, a nodular blush compatible with luxury perfusion of a subacute infarct was visible in the posterior right thalamic region.

The patient was started on aspirin. At discharge, the patient had a mild residual left-sided weakness. At 1 month follow-up visit, the patient showed only slightly decreased fine fractionated movements in the left hand. Her gait was normal, with the exception of an occasional high-amplitude, low-frequency tremor that caused some difficulty when she was walking on her toes. This tremor was also noted when the patient had her arms outstretched and pronated. This tremor, characteristic after thalamic infarcts (Holmes’ tremor), began approximately 3 weeks after initial presentation.

Case 3

A 19-month-old boy with no significant medical history began complaining of left-sided headache after an uneventful day at daycare. He started to cry and vomited once before going to sleep for the night. He was difficult to arouse the next morning, was not using his right hand,
and refused to bear weight on his legs. His primary care physician noted decreased use of his right hand and leg, decreased right visual field, and mild right-sided drooling. There was no definite history of trauma. At admission in the emergency department, he had a right homonymous hemianopsia and a mild right hemiparesis. Noncontrast brain CT showed hypoattenuation in the left occipital lobe as well as in the left thalamus, compatible with a left PCA territory infarct (Fig 3A). MR imaging demonstrated restricted diffusion compatible with an acute infarct in the medial aspect of the left occipital lobe and lateral aspect of the thalamus (Fig 3B). MR angiography showed absence of flow-related enhancement in the left PCA distal to the P1-P2 junction. DSA demonstrated a patent but irregular and narrowed left PCA, distal to the posterior communicating artery termination (Fig 3C), with delayed filling of its distal distribution and occlusion of the calcarine artery. Findings of transthoracic echocardiography were unremarkable, as was the result of screening for hypercoagulability disorders. The patient was maintained on 81 mg of aspirin per day throughout his hospital course and showed mild improvement of his hemiparesis and a decrease in his visual field deficit. The patient did not return for further follow-up at our institution.

Discussion

Although most arterial dissections or dissecting aneurysms remain without detectable cause, a possible causative relation has been suggested with conditions such as syphilis, migraine headaches, cystic medial necrosis, Marfan syndrome, mixed connective tissue disease, fibromuscular dysplasia, homocystinuria, polycystic kidney disease, and trauma.6,14,16,18 Although arterial hypertension has commonly been associated with extracranial carotid dissection, few patients with posterior circulation dissection are found to be hypertensive.6,19 In 2 of our patients, the onset of symptoms shortly followed a minor head trauma without loss of consciousness. Interestingly, the mechanism of trauma was similar, yet somewhat unusual in both cases, with an axial impact on the top of the head. The temporal relationship between the traumatic

...The diagnosis of intracranial dissection and dissecting an-
...graphic appearance of the lesion—that is, focal stenosis in case of intracranial dissection and pseudoaneurysm development in case of extracranial dissection. A focal stenosis, with or without a poststenotic dilation, occurs as the hematoma tracks between the internal elastic membrane and the media, causing mass effect on the lumen without disrupting the outer media or adventitia. Rarely, intracranial dissections may involve the subadventitia and rupture into the subarachnoid space. In the extracranial arteries, the hematoma tracks in the outer media and between the media and adventitia, thus narrowing the vessel lumen but also leading to pseudoaneurysm formation, with the hematoma contained by the adventitia.

Absence or dysplasia of the internal elastic lamina, especially if the media is incomplete, is believed to predispose to intracranial dissection. Isolated PCA dissections most commonly occur near the P1-P2 junction, which is close to the free border of the tentorium cerebelli. It has been suggested that traumatic aneurysms, including dissections, may occur in mild head trauma secondary to a stretch or shear injury of the vessels. In 2 of our patients, the location of the PCA dissection and the association with mild head trauma lend credence to a posttraumatic cause of intracranial dissections. In the third patient, no definite trauma was documented but the dissection occurred in the same location.

The diagnosis of intracranial dissection and dissecting aneurysms is predominantly made by DSA, which remains the gold standard technique. There is narrowing of the vascular lumen secondary to the subintimal hematoma (string sign), with or without segmental dilation proximal or distal to the stenosis (string and pearl sign). The lumen is often irregular or asymmetrical. If the intramural hematoma becomes large enough, occlusion can occur. A pathognomonic double lumen sign, as documented in our first patient, is less frequently seen; it represents antegrade flow in both the true and false lumens, which are separated by the intimal flap. It has been suggested that the predominantly stenotic lesions more often present with ischemic symptoms, whereas the predominantly dilated lesions more likely present with bleeding. A change in the appearance of the vessel lumen with time is also characteristic. Noncontrast CT should be performed at initial presentation primarily to evaluate for hemorrhage and also to assess for large infarction. Subarachnoid hemorrhage is present in approximately 25% of cases. MR imaging should also be performed for definitive evaluation of stroke.

Although MR angiography has been reported to be a reliable method for establishing the diagnosis of intracranial ar-
irregularity or narrowing is often a nonspecific finding. T1-weighted images may show high signal intensity within the dissected vessel wall, but the signal intensity of the hematoma changes with chronologic age of the bleed and is seen in a dissected vessel wall, but the signal intensity of the hematoma weighted images may show high signal intensity within the irregularity or narrowing is often a nonspecific finding. T1-old and 19-month-old patients. Pozzati et al8 reported 2 cases favorably to intravenous heparin. We opted for more conserva-
issimic symptoms. Our 47-year-old patient responded fa-
terior dissection,11 the technique is limited by the small caliber of the intracranial vessels and often by patient motion artifact. In addition, the appearance of vessel wall
atric dissection,11 the technique is limited by the small caliber of the intracranial vessels and often by patient motion artifact. In addition, the appearance of vessel wall
patients, it is important to maintain adequate blood pressure control to prevent progression of the dissection and possible rebleeding or worsened ischemia.
Patients with ruptured dissecting aneurysms and associ-
ated subarachnoid hemorrhage or progressive neurologic deficits typically require treatment by surgical or endovascular means.17 Surgical treatment of dissecting aneurysms includes excision, trapping, proximal ligation, and reinforcement with or without intracranial-extracranial bypass.6,8,18,21 Repeated intramural hemorrhage or enlargement of an associated aneur-
ysm also requires surgical intervention.16 However, Pozzati et al8 noted spontaneous healing in 2 patients with subarachnoid hemorrhage, who had fusiform dissecting aneurysms of the PCA. They suggested that this shape of dissecting aneurysm lies at the more benign end of the clinical spectrum.
Maillow15 also reported a case of spontaneous resolution with complete recanalization of a dissecting PCA aneurysm. Endovascular options for the treatment of arterial dissections include stent placement or therapeutic occlusion by using detachable microcoils and/or balloons.
Endovascular treatment for dissecting aneurysms of the posterior circulation and specifically for PCA dissecting aneu-
rysm has been described.17,22-24 Although endovascular treat-
ment has been performed only in a small number of patients, it seems to offer a reasonable alternative to surgery.

**Fig 3.** 19-month old boy presenting with right hemiparesis. 
A, Axial noncontrast head CT demonstrating hypodensit-
ation in the medial aspect of the left occipital lobe involving the cortex and subcortical white matter with loss of gray-white matter differentiation. 
B, Axial DWI showing corresponding restricted diffusion compatible with infarct. There was respective low signal intensity on the apparent diffusion coefficient map (not shown). 
C, DSA, right vertebral artery injection, transfacial image demonstrating an irregular and narrowed left proximal PCA.
