Stenoses in Idiopathic Intracranial Hypertension: To Stent or Not To Stent?

I read with great interest the paper entitled “Reversibility of Venous Sinus Obstruction in Idiopathic Intracranial Hypertension” recently published in the American Journal of Neuroradiology by Rohr et al.1 This paper presents the case histories of 3 patients with idiopathic intracranial hypertension (IIH) and venous outflow stenoses. The first patient had an initial resolution of her symptoms after insertion of a stent into the transverse sinus, but the symptoms recurred and a restenosis was noted just upstream from the stent. This patient was later treated with insertion of a shunt tube. In the second and third cases, the patients were treated with insertion of a shunt, with the venous stenoses in the second patient improving after the insertion. On the basis of these cases, the authors suggest that the elevated venous pressure in IIH is caused by the collapse of the sinuses.3 They go on to assert that insertion of a stent should be reserved for fixed stenoses and should not be used for dynamic stenoses. This suggestion is proposed because, logically, if the raised pressure in the CSF has caused the collapse of the venous sinus, then the elevated venous pressure cannot also be the cause of the raised CSF pressure. I wish to discuss whether the cause-and-effect relationship, as outlined, is the only one possible given the data as presented.

Most patients with IIH have morphologic stenoses in the venous outflow.2 Many of these stenoses reduce the outflow by more than 70% in area and would be deemed significant if found on the arterial side of the vascular tree. Direct manometry has shown the pressure gradients across these stenoses to average 24 mm Hg,3 which would side of the feedback loop (ie, reducing the CSF pressure with placement of a shunt or stent into an overly compliant transverse sinus will break the loop). Thus, I believe that the assertion by Rohr et al1 that placement of a stent should not be offered to patients who have IIH and collapsible stenoses is not necessarily correct. The only proviso is that the stent must support all of the compliant sections of the venous system or the stenosis will recur (well documented by the authors in patient 1). Ultimately, whether the front-line treatment of IIH associated with collapsible venous outflow is stent placement or shunt insertion will depend on the relative morbidity of these procedures and their long-term rates of success.

Because venous sinus stenoses in idiopathic intracranial hypertension (IIH) can be reversed by lowering the intracranial pressure, I believe that these stenoses are caused primarily by elevated intracranial pressure. I think there might, furthermore, be a feedback mechanism in IIH such that an increase in intracranial pressure (due to impaired absorption of CSF?) leads to stenoses of the transverse sinuses and that these stenoses lead to an increase in intravenous pressure proximal to the stenoses (which can be measured directly by a catheter). This again could hamper absorption of CSF, leading to a further increase in pressure. (In theory, pressure would then rise infinitely, but in reality it does not. Therefore, the mechanisms must be somewhat more complex.) We saw cases of secondary intracranial hypertension demonstrating narrowing of large segments of the intracranial sinuses, whereas in IIH, there seems to be a predilection for the development of the stenoses in the lateral parts of the transverse sinuses. Therefore, patients with IIH probably have some pathoanatomic change in this region of the sinus (“vulnerable segments” may be secondary to hormonal changes).

I agree with Bateman that patients might profit from stent angioplasty, which interrupts the feedback mechanism. However, the problem is—as he stated and as our first patient demonstrated—that stent angioplasty might be necessary for all the “vulnerable” segments of the intracranial sinuses. Moreover, we probably tackle only a part of the problem with this procedure. On the other hand, there might be a subgroup of patients with IIH who have fixed sinus stenoses (eg, originating in venous sinus thrombosis) predisposing them for stent angioplasty. We have to prove though that these groups of patients really exist.

I also think there is a need for a randomized controlled multicenter trial in which the performance of stent angioplasty versus shunt surgery procedures is compared in patients with pharmaco-
