Intracranial Internal Carotid Artery Calcifications: Association with Vascular Risk Factors and Ischemic Cerebrovascular Disease

BACKGROUND AND PURPOSE: Atherosclerotic calcifications are present not only in the extracranial carotid bifurcation but also in the intracranial part of the internal carotid artery. We assessed the association between intracranial internal carotid artery calcifications and cardiovascular risk factors in patients with ischemic cerebrovascular disease and the association between calcifications and the presence of this disease.

MATERIALS AND METHODS: Patients undergoing multidetector CT (MDCT) angiography of the carotid arteries for assessment of stenosis degree were included in the study. A semiautomated custom-made system to quantify calcifications was developed. The associations between the volume of calcifications and cardiovascular risk factors and the type of ischemic cerebrovascular disease were assessed with logistic regression.

RESULTS: MDCT angiography was performed in 406 patients (age, 62 ± 14 years; 242 men). Men had a significantly higher calcification volume (66 mm³) than women (33 mm³). Calcification volume was positively associated with age in both men and women. Smoking, hypercholesterolemia, and a history of cardiac disease were independently related to the presence of calcifications. A history of cardiac disease and ischemic cerebrovascular disease were independently related to the volume of calcifications. No association was found between calcifications and the presence of type of ischemic cerebrovascular disease in the vascular territory of the intracranial internal carotid artery.

CONCLUSIONS: Calcifications were associated with higher age and male gender. The presence and volume of calcifications were independently associated with cardiovascular risk factors. Calcifications were not related to the presence or type of ischemic cerebrovascular disease.
Scanning and Image Reconstruction

Scanning was performed on a 16-section MDCT scanner (Sensation 16; Siemens, Erlangen, Germany) with a standardized optimized contrast-enhanced protocol (120 kilovolt [peak]; 180 mAs; collimation, 16 × 0.75 mm; table feed, 12 mm/rotation; pitch, 1). The MDCTA scanning range reached from the ascending aorta to the intracranial circulation (2 cm above the sella turcica). All patients received 80-mL contrast material (iodixanol, 320 mg/mL, Vistopaque; Amersham Health, Little Chalfont, UK), followed by a 40-mL saline bolus chaser, both with an injection rate of 4 mL/s. Synchronization between the passage of contrast material and data acquisition was achieved by real-time bolus tracking at the level of the ascending aorta.

Image reconstructions were made with an FOV of 100 mm; matrix size, 512 × 512 (real in-plane resolution, 0.6 × 0.6 mm); section thickness, 1.0 mm; increment, 0.6 mm, with an intermediate reconstruction algorithm.

Analysis of Intracranial Internal Carotid Artery Calcifications

A trained reader (H.C.) who was blinded to the clinical data of the patients performed the quantification of the calcifications in both intracranial internal carotid arteries. A second trained reader (T.T.d.W.) evaluated independently 100 patients to assess interobserver variability. The intracranial internal carotid artery comprised the horizontal segment of the petrous internal carotid artery to the top of the carotid artery (Fig 1).

The volume of calcifications was measured with the custom-made polymrasure plug-in for the freely available software ImageJ (developed by Wayne Rasband; National Institute of Mental Health, Bethesda, Md; available at: http://rsb.info.nih.gov/ij). This plug-in made it possible for an observer to draw polygonal regions of interest in consecutive axial MDCTA images and to calculate automatically the total number of pixels above a predefined HU value within the region of interest (Fig 2). The threshold value for calcification was set at 500 HU, which is above the normally used value of 130 HU for the Agatston score. This threshold was chosen to enable an automatic differentiation between contrast material in the lumen, which was <500 HU, and calcifications in the vessel wall. In case a calcification was close to the skull base, care was taken to delineate the calcification and to include it in the region of interest (Fig 3). The volume of calcifications was calculated by multiplying the number of pixels above the threshold (500 HU), the pixel size, and the increment.

Cardiovascular Risk Factors

Clinical measures and information on risk factors and medication were obtained at admission to the hospital or, in cases in which measurements at this time point could be biased (eg, blood pressure at...
admission), they were derived from clinical history or obtained at discharge. Subjects were categorized as ever (including present) or never smokers. Hypertension was defined as a mean systolic blood pressure ≥140 mm Hg and/or mean diastolic blood pressure ≥90 mm Hg during 2 episodes of at least 15 minutes of continuous non-invasive blood pressure measurement or as treatment with antihypertensive medication (ie, angiotensin converting enzyme inhibitors, calcium antagonists, beta-blockers, and diuretics). Hypercholesterolemia was defined as fasting cholesterol ≥5.0 mmol/L or as treatment with cholesterol-lowering drugs. Diabetes was defined as fasting serum glucose levels ≥7.9 mmol/L, nonfasting serum glucose levels ≥11.0 mmol/L, or the use of antidiabetic medication. Information on a history of cardiovascular disease (defined as a clinical diagnosis of myocardial infarction, atrial fibrillation, angina pectoris, chronic heart failure, or coronary artery bypass grafting) and a history of ischemic cerebrovascular disease (defined as a clinical diagnosis of amaurosis fugax, TIA, or ischemic stroke) was collected.

**Symptoms**

Amaurosis fugax was defined as a sudden loss of vision of presumed vascular origin and confined to 1 eye. TIA was defined as a sudden focal neurologic deficit that was presumed to be of vascular origin and was confined to an area of the brain perfused by a specific artery and that was resolved within 24 hours. In addition, no relevant infarct (1 that explains the deficit) was visible on the CT scan. An ischemic
stroke was defined as a sudden focal neurologic deficit that lasted >24 hours or that was accompanied by a relevant infarct on the CT scan.

Statistics

Data are presented as mean ± SD. Baseline characteristics between men and woman were evaluated for differences. Interobserver differences in volume measurements were presented with an intraclass correlation coefficient, a coefficient of variation (defined by the SD of the paired difference divided by the mean of the absolute value), and a Bland-Altman plot. Differences between categoric data and continuous data were analyzed with a χ² test and a Mann-Whitney U or Student t test, respectively. The Spearman correlation coefficient was used to analyze the association between age and calcifications for men and women. Logistic regression was used to evaluate the association between cardiovascular risk factors and calcifications. The presence of calcifications (left and right summated) was compared with the absence of calcifications, and the highest quartile of calcification was compared with the lower 3 quartiles. First, the regression analysis was adjusted only for age and sex. Second, additional adjustments were made for all risk factors.

The volume of intracranial calcifications in the left and right and in symptomatic and asymptomatic internal carotid arteries was compared with a paired t test. The association between the volume of intracranial calcifications in the symptomatic internal carotid artery and the type of cerebral vascular disease was assessed with logistic regression analysis with adjustment for age, sex, and cardiovascular risk factors.

Results

A total of 406 patients with amaurosis fugax, TIA, or minor ischemic stroke was analyzed. Patient characteristics are shown in Table 1. There were no significant differences between men and women in age, symptomatic artery, and ischemic cerebrovascular symptoms. However, men were more often smokers and had more often experienced cardiac disease; women had more often experienced hypercholesterolemia.

The intraclass correlation coefficient for the assessment of intracranial calcifications was excellent (0.99), and the coefficient of variation for the interobserver differences was very low (7%). Absolute differences between observers were low and did not depend on the size of the calcifications (Fig 4).

Intracranial internal carotid artery calcifications were more frequent in men than in women (71% and 56%, respectively; *P* < .003), and they were larger in men (66 ± 124 mm³ and 33 ± 91 mm³, respectively; *P* < .001). Figure 5 shows the

association between age and calcifications for both men and women with a Spearman $\rho$ of 0.548 ($P < .001$) for men and 0.501 ($P < .001$) for women and 0.531 ($P < .001$) for men and women together.

Table 2 presents the age- and sex-adjusted and multivariate-adjusted odds ratios for the associations between cardiovascular risk factors and intracranial calcium volume. Smoking, hypercholesterolemia, and a history of cardiac disease were independently associated with the presence of intracranial internal carotid artery calcifications. A history of cardiac disease and a history of ischemic cerebrovascular disease were independently associated with the highest quartile of intracranial calcium volume.

There was no significant difference between the intracranial calcium volumes of the left and right carotid arteries ($P = .97$). Table 3 provides the intracranial calcium volume for the symptomatic and contralateral asymptomatic internal carotid artery and the intracranial calcium volume in the symptomatic internal carotid arteries of patients with amaurosis fugax, TIA, and minor ischemic stroke. No significant differences were found in intracranial calcium volumes at the symptomatic and asymptomatic side ($P = .73$). In a logistic regression analysis adjusted for age, sex, and all risk factors, intracranial calcifications were not related to the type of symptoms (amaurosis fugax versus TIA or minor stroke).

**Discussion**

This study shows that a dedicated custom-made software tool can reproducibly quantify intracranial internal carotid artery calcifications. Furthermore, it shows that the presence of intracranial calcifications is associated with smoking, hypercholesterolemia, and history of cardiac disease and that the severity of calcifications is related to a history of cardiac disease and a history of ischemic cerebrovascular disease.

No difference was found in the volume of intracranial calcifications between the symptomatic and asymptomatic internal carotid arteries and in the volume of intracranial calcifications in the symptomatic artery between patients with amaurosis fugax and those with TIA or minor stroke.

Previous studies8–12 had a binary or a qualitative (5-point scale) grading system for classification of intracranial calcifications, probably because quantification difficulties arose due to the close relationship between calcifications and the bony structures of the skull. Taoka et al13 were able to use commercially available software for quantification of intracranial calcifications, but they had to eliminate the contamination of bone attenuation on wide-windowed CT images. We dealt with this problem by developing a custom-made software tool that allowed manual segmentation of intracranial calcifications without contamination of the bony skull, and we assessed the volume of calcifications instead of the Agatston score. Because this quantification method was HU-based, the manual outline of the border between calcifications and skull was the only time-consuming part. However, this border was, in most cases, clearly visible, enabling the segmentation per patient to be done relatively quickly (<15 minutes). Observer differences were caused by the differences in the manual outline of the border between calcifications and skull. The very low observer variability indicates that observers did recognize the same hyperattenuated areas as possible calcifications and...
that their manual outlines between calcifications and skull were very similar.

Our study in patients with ischemic cerebrovascular symptoms and a mean age of 73 years revealed a prevalence of intracranial internal carotid artery calcifications of 65%. Age, sex, smoking, hypercholesterolemia, a history of cardiac disease, and a history of ischemic cerebrovascular disease were independently related to the presence or volume of intracranial internal carotid artery calcifications. Associations between cardiovascular risk factors and intracranial calcifications have been studied in patients referred for brain CT.10-12 One study found an independent association between sex and intracranial internal carotid artery calcifications,11 whereas another study did not find this association.10

In the present study, we found that smoking and hypercho-

lesterololemia are independently associated with the presence of intracranial calcifications. Other studies showed independent associations of smoking with coronary, aortic arch, carotid bifurcation calcifications and intracranial internal carotid artery calcifications. Hoff et al found, in a large study among asymptomatic individuals, an independent association of hypercholesterolemia with coronary calcification in both men and women. However, a study by Allison et al examining risk factors for coronary, proximal aorta, and carotid calcifications found no independent associations with hypercholesterolemia. An independent association between hypertension and coronary calcifications, aortic arch calcifications, and carotid bifurcation calcifications has been described; however, the present study did not find an association between hypertension and the presence of intracranial carotid calcifications or an association between the presence of calcifications and diabetes, as is known from coronary literature. A possible explanation for the absence of such associations could be the fact that we are dealing with a fundamentally different pathophysiology. In the intracranial arteries, atherosclerotic calcifications normally develop within the vessel wall, with little noncalcified atherosclerotic components and little luminal compromise, whereas in the coronary arteries, the calcified parts in the plaque are accompanied by extensive noncalcified components and considerable luminal narrowing.

Internal carotid artery calcifications might be an indicator of arterial stenosis. Stenosis in the intracranial internal carotid artery carries an increased risk of stroke. Therefore, we compared the volume of calcifications in the symptomatic and asymptomatic internal carotid arteries; however, no difference in intracranial calcium volume was found between the symptomatic and asymptomatic side. This is in agreement with Babiarz et al, who found no differences in the scores ipsilateral and contralateral to the stroke. In addition, in 2 cross-sectional studies, they found that intracranial internal carotid artery calcifications were not independently related to the extent of white matter lesions or the presence of stroke. In a follow-up study of 72 patients, Taoka et al did not find an association between the intracranial internal carotid artery calcifications score and the later occurrence of stroke. Therefore, they concluded that intracranial calcifications should not be considered as the cause of an ischemic event by being a source of embolism or thrombosis, but they should be considered as a marker of systemic atherosclerotic disease, which is closely related to stroke.

A limitation of the present study was that it is still labor-intensive to draw a region of interest on each image that shows an intracranial internal carotid artery calcification; therefore, a tool should be developed that locates the calcification and quantifies it automatically. A second limitation is the lack of a gold standard. The accuracy of MDCTA-based assessment of the presence and volume of intracranial internal carotid artery calcifications could, therefore, not be established. However, the ability to determine and quantify calcifications accurately has been proved in other vascular beds. Another limitation is that the calcium volume in the intracranial contralateral carotid artery of patients with ischemic cerebrovascular symptoms has been used in the analysis as the asymptomatic volume, instead of the calcium volume in the intracranial carotid arteries of completely asymptomatic patients. Finally, we could not, due to ethical reasons, include patients with severe stroke especially because their data would contain relevant information on who was at risk of developing a severe stroke.

This study showed that, with custom-made software, quantitative evaluation is reproducible. Therefore, follow-up studies should explore the association between the presence and volume of intracranial internal carotid artery calcifications and (recurrent) ischemic cerebrovascular events. Furthermore, these studies should assess the additional value of this measure over commonly used parameters in the prediction of ischemic cerebrovascular events, as well as its value as a marker of systemic atherosclerotic disease.

Conclusions

Our study showed that intracranial internal carotid artery calcifications can reproducibly be quantified with a dedicated custom-made software tool and that age, sex, smoking, hypercholesterolemia, a history of cardiac disease, and a history of ischemic cerebrovascular disease are independently related to the presence or volume of arterial calcifications. Furthermore, we showed that the degree of calcifications does not differ between the symptomatic and contralateral asymptomatic arteries and that calcifications are not related to presence or type of ischemic cerebrovascular disease.
