Role of Aqueductal CSF Stroke Volume in Idiopathic Normal-Pressure Hydrocephalus

I read with great interest the article by Scollato et al entitled “Changes in Aqueductal CSF Stroke Volume in Shunted Patients with Idiopathic Normal-Pressure Hydrocephalus.” In this study, the authors investigated whether there is a relationship between clinical outcome and changes in aqueductal CSF stroke volume (ACSV) in patients with idiopathic normal-pressure hydrocephalus (INPH) who have undergone shunting. I would like to thank the authors for presenting such a comprehensive study performed in a large series.

INPH is generally seen in the elderly and is characterized by gait disturbance, dementia, and urinary incontinence with normal opening pressure at lumbar puncture in patients without causative disorders and ventricular enlargement due to disturbed CSF circulation. Some symptoms may resolve with CSF diversion, so there are studies aimed at identifying patients who would respond to shunt treatment.

Scollato et al showed that “INPH shunt responders presented higher preshunt ACSV values and shorter onset times of symptoms with respect to nonresponders.” They also described an increase of ACSV (reversible phase) in the early period and a decrease in the late period among patients with INPH in their previous study. In this study, low ACSV values in unshunted patients were noted to be an indicator of irreversible neuronal damage occurring secondary to ischemia. The underlying cause of cerebral ischemia has been noted to be the reduction of flow in periventricular arterioles due to tangential and radial shearing force developing secondary to progressive ventriculomegaly. After the shunt therapy, the pressure reflected on periventricular arterioles decreases and cerebral ischemia resolves. Increase in cerebral perfusion occurring after the shunt may explain the clinical improvement in these patients.

Although in many studies cerebral ischemia is centered in the pathophysiology of INPH, ischemia is not present in all INPH cases. In their study with MR imaging and positron-emission tomography, reported that cerebral blood flow (CBF) is 19% decreased in patients with INPH compared with the control group. However, in this study, the SD of the data was high, and CBF was normal in 15% of patients with INPH. The CBF measurements in patients with INPH and the control group suggest that ischemia is not a prerequisite for generation of INPH. It is not known if ischemia is the cause or the effect of the disease. The general concept is that decreased CBF causes neuronal loss. In the literature, it is reported that CBF is normal in 15% of patients with INPH. In patients with low CBF (global ischemia), a shunt procedure does not always increase CBF and no significant correlation has been shown between relief of symptoms and CBF.

ACSV measurement is a noninvasive test that benefits INPH diagnosis. The recent article of Scollato et al showed that “INPH shunt responders presented higher preshunt ACSV values and shorter onset times of symptoms with respect to nonresponders.” Also, Kim et al determined a decrease in CSF stroke volume among patients with INPH following shunt therapy. In their recent report, Scollato et al stated, “This study shows that ACSV may be a useful noninvasive tool for the preoperative selection of patients with INPH.” Unfortunately, the relationship between the response to shunt treatment and ACSV value could not be fully understood. ACSV and velocity values have been reported to be inefficient in the prediction of shunt response by several authors. While the drop in ACSV values appears to be higher in patients benefiting from shunt than in those who do not, no definitive ACSV limit value has been described for deciding to perform a shunt treatment. Therefore, I agree with the conclusion of Scollato et al that ACSV measurements are useful in monitoring the response following shunt treatment. Nonetheless, I agree with the conclusion of Scollato et al that ACSV measurements are useful in monitoring the response following shunt treatment. Moreover, as mentioned by Scollato et al, I believe that ACSV measurements can be beneficial in the evaluation of shunt function and in the detection of the complications such as subdural fluid collection.

In light of the results of the study conducted of Scollato et al, I think new studies should focus on the correlation between ACSV and cerebral perfusion. Those studies may shed light on whether ischemia is the cause or outcome of INPH.

In conclusion, despite hundreds of studies conducted in the past years, investigators have failed to reveal the etiopathogenesis and shunt indication of INPH disease. Currently, there is no test that can establish a definitive diagnosis or predict shunt response. Determination of ACSV is noted as a method that is helpful in INPH diagnosis and therapy monitoring. I believe that to determine phase-contrast MR imaging parameters that can predict the shunt response, further comprehensive studies with larger series are needed.
