Differentiation of Recurrent Tumor and Posttreatment Changes in Head and Neck Squamous Cell Carcinoma: Application of High b-Value Diffusion-Weighted Imaging

*AJNR Am J Neuroradiol* 2013, 34 (12) 2343-2348
doi: https://doi.org/10.3174/ajnr.A3603
http://www.ajnr.org/content/34/12/2343
Background and Purpose: High b-value DWI has been expected to have an additional diagnostic role and demonstrated some promising results in head and neck cancer. The aim of this study was to evaluate the diagnostic performance of DWI at a high b-value (b = 2000 s/mm²) compared with a standard b-value (b = 1000 s/mm²) and the ratio of ADC values of high and standard b-values for their ability to differentiate between recurrent tumor and posttreatment changes after the treatment of head and neck squamous cell carcinoma.

Materials and Methods: A total of 33 patients diagnosed with head and neck squamous cell carcinoma were enrolled in the present study; all had contrast-enhancing lesions on follow-up MR imaging. All patients underwent single-shot echo-planar DWI at b = 1000 s/mm² and b = 2000 s/mm², and corresponding ADC maps were generated (ADC1000 and ADC2000, respectively). The mean ADC1000, ADC2000, and ADCratio (ADCratio = ADC2000/ADC1000 × 100) values were evaluated within a manually placed ROI with contrast-enhanced T1-weighted images as references. For the statistical analysis, we performed a Student t-test and multivariate logistic regression.

Results: The mean ADC1000 in recurrent tumor was significantly lower than that in posttreatment changes (P < .001), whereas the mean ADC2000 resulted in no significant difference (P = .365). The mean ADCratio was significantly higher in recurrent tumor than that in posttreatment changes (73.5 ± 7.2% vs 56.9 ± 8.8%, respectively; P < .001). Multivariate logistic regression analysis revealed that the ADCratio was the only independently differentiating variable (P = .024). The sensitivity, specificity, and accuracy of ADCratio were 95.0%, 69.2%, and 84.8%, respectively, by use of the optimal cutoff value of 62.6%.

Conclusions: We suggest that the ADCratio calculated from the ADC1000 and ADC2000 is a promising value for the differentiation of recurrent tumor and posttreatment changes in head and neck squamous cell carcinoma.

Abbreviations: ADC1000 = ADC value calculated at b = 0 and 1000 s/mm²; ADC2000 = ADC value calculated at b = 0 and 2000 s/mm²; ADCratio = ratio of ADC2000 over ADC1000; HNSCC = head and neck squamous cell carcinoma

Imaging surveillance after treatment of head and neck squamous cell carcinoma (HNSCC) is useful to detect residual or recurrent tumor, even when clinical recurrence is not suspected. In these patients, however, the multidisciplinary treatment with surgery, radiation therapy, and/or chemotherapy that improves patient survival and quality of life complicates interpretation of posttreatment follow-up imaging studies because surgery can alter anatomy and radiation therapy and chemotherapy can result in edema and fibrosis. These posttreatment changes can mimic tumor recurrence, and sometimes it is difficult to distinguish these from residual or recurrent tumor on CT or MR images.

Diffusion-weighted imaging (DWI) is based on the Brownian motion of water protons in the tissue, which is affected by the microstructure of tissue. Several previous studies support the value of applying DWI in head and neck cancer for the differentiation and characterization of primary tumor, nodal staging, and the prediction of treatment response. In addition, several promising studies have been reported on the usefulness of DWI in the discrimination between recurrent or residual tumor and posttreatment changes. These studies have demonstrated that performing DWI and measuring the ADC value could be helpful in differentiating residual or recurrent tumor from posttreatment changes.
suring the ADC values may enable differentiation of residual or recurrent tumor from posttreatment changes.

In recent years, high b-value (b > 1000 s/mm²) DWI was introduced along with improvements in MR imaging gradient technology. These high b-value techniques have demonstrated promising results in brain imaging compared with the standard b-value (b=1000 s/mm²) DWI. In head and neck cancer, a previous study introduced a ratio of the ADC values from high and standard b-value DWI and suggested that it correlates with the maximal standardized uptake value from FDG-PET. Another published study revealed that high b-value DWI is helpful in the differentiation of histologic grades in HNSCC.

The aim of our present study was to evaluate the additional role and diagnostic performance of high b-value (b=2000 s/mm²) DWI compared with standard b-value (b=1000 s/mm²) DWI, and the ratio of ADC values from high and standard b-values for the differentiation between recurrent tumor and posttreatment changes after treatment of HNSCC.

MATERIALS AND METHODS

Study Population

Our hospital institutional review board approved this retrospective study, and the requirement for informed consent was waived. A total of 1331 patients with head and neck cancer underwent head and neck MR imaging our institution between January 2010 and February 2012. Among them were 351 patients with pathologically confirmed HNSCC. After retrospectively reviewing the electronic medical records, we included 56 patients matching these inclusion criteria: 1) the patient underwent MR imaging with standard and high b-value DWI after treatment of HNSCC; 2) the term between the end of treatment and posttreatment imaging was longer than 6 weeks, to avoid very early posttreatment changes; 3) there was newly developed or increased enhancing portion on postcontrast T1-weighted images where recurrence was highly suspected or indeterminate; and 4) the lesion was large enough to measure on MR imaging (diameter ≥ 5 mm). A total of 23 patients were further excluded from our study population because of degradation of image quality (eg, susceptibility artifacts that distort the area of concern partly or completely) (n=15), incomplete medical history because of loss to follow-up (n=7), and a history of additional malignant disease outside of the head and neck area (n=1). Finally, we included 33 patients (18 men, 15 women; mean age, 60.2 years; age range, 30–78 years). The primary tumor locations were the oral cavity (n=16), oropharynx (n=4), sinonasal cavity (n=5), nasopharynx (n=3), hypopharynx (n=2), and external auditory canal (n=3). Various surgical procedures or radiation therapy techniques were performed according to the disease extent and location, with the following treatments: surgery alone (n=9); both chemotherapy and radiation therapy (n=7); surgery and postoperative radiation therapy (n=13); and a combination of chemotherapy, surgery, and radiation therapy (n=4). In our institution, most of the patients treated for head and neck cancer are monitored with MR imaging routinely. Thirteen patients underwent MR imaging earlier than the scheduled date because of clinical suspicion of recurrence (eg, palpable mass or visible lesion on endoscopy; tumor recurrence in 12 patients, posttreatment changes in 1 patient). MR imaging was obtained in 1 patient because of a visible mass at the oral cavity on physical examination; this was followed by MR imaging for 2 years without change, suggesting posttreatment change. All other patients underwent MR imaging as a routine follow-up technique.

Determination of Recurrent Tumor vs Posttreatment Changes

Recurrent tumor and posttreatment changes were differentiated with clinical or histopathologic characterization as follows:

Histopathologic Diagnosis. We obtained the pathologic diagnosis by reviewing the institution electronic medical records. The institution pathologists, who had at least fellowship training in reading head and neck pathologic changes, made these pathology reports. Histopathologic evaluation was performed in 19 cases; 17 and 2 were confirmed as recurrent tumor and posttreatment changes, respectively. Pathologic diagnoses for those 2 patients were chronic hyperplastic candidiasis and chronic active inflammation, and these patients had no evidence of recurrence during subsequent follow-up at 22 months and at 15 months, respectively.

Clinical Diagnosis. In patients without histopathologic evaluation during follow-up, tumor recurrence was defined by clinical criteria. In 3 cases, recurrent tumors were clinically determined based on growth of an enhancing lesion by at least 20% or more on the subsequent follow-up image. Posttreatment lesions (n=11) were clinically defined as no change or a decrease in size of the enhancing lesion and no other evidence of recurrence during at least 1 year of follow-up (mean follow-up time, 24 months; range, 15–39 months).

MR Imaging Acquisition

All patients underwent MR imaging by use of a 1.5T MR imaging system (Signa Excite, HDx or HDxt; GE Healthcare, Milwaukee, Wisconsin) with an 8-channel head and neck coil. A transverse T1-weighted spin-echo sequence was performed with the following parameters: TR range, 550–560 ms; TE range, 10–12 ms; 30–36 sections; section thickness, 4 mm; intersection gap, 1.2 mm; FOV, 220 × 220 mm; matrix, 320 × 192; acquired signal, 1; and pixel resolution, 0.7 × 1.1 × 4.0 mm. The contrast-enhanced transverse T1-weighted spin-echo sequences with fat suppression were also acquired after the intravenous injection of 0.1 mmol/kg of gadopentetate dimeglumine (Magnevist; Bayer Schering Pharma, Berlin, Germany). Additional coronal and sagittal T1-weighted sequences were performed with identical imaging parameters after administration of contrast agent.

The single-shot echo-planar DWI was obtained in the transverse plane before contrast material injection at both the standard b-value (b=0 and 1000 s/mm²) and high b-value (b=0 and 2000 s/mm²) with the following parameters: TR range, 8000–10,000 ms and TE range, 61.6–77.6 ms (at b=1000 s/mm²); TR range, 9325–12,000 ms and TE range, 73.8–90.4 ms (at b=2000 s/mm²); 30–45 sections; section thickness, 4 mm; intersection gap, 1.2 mm; bandwidth, 153 Hz/pixel; FOV, 240 × 240 mm; matrix, 160 × 160; acquired signal, 2; and pixel resolution, 1.5 × 1.5 × 4.0 mm. DWI data were acquired in 3 orthogonal directions and combined into a trace image. The average durations of DWI at b=0 and 1000 s/mm² and b=0 and 2000 s/mm² were 1 min 23 s and 2 min 50 s, respectively.

The corresponding ADC maps were automatically derived from the following equation on the Advantage workstation (GE Healthcare): \( ADC = -\ln[S(b)/S(0)]/b \), where b is the diffusion-
interpreting head and neck MR images, respectively, in which the tors (I.H. and S.H.C. with 2 years and 10 years of experience in developed software.

Clinicopathologic Characteristics

In our study population, recurrent tumor was found in 20 patients and posttreatment changes were found in 13 patients. There were more male patients in the recurrent tumor group (M:F = 14:6) vs the posttreatment changes group (M:F = 4:9). In the recurrent tumor group, MR imaging was obtained mainly because of clinical suspicion of recurrence, whereas MR imaging was mostly performed in a routine follow-up manner in the group with posttreatment changes (Table 1). Otherwise, no significant difference was observed in mean age, mean ROI size, and mean interval from completion of therapy to follow-up imaging between the recurrent tumor group and the group with posttreatment changes (Table 1). The mean imaging follow-up time of the group with posttreatment changes was 23 months, and no patient had recurrence during the follow-up period.

Comparison of ADC1000, ADC2000, and ADCratio between Patients with Recurrent Tumor and Patients with Posttreatment Changes

Table 2 and Fig 1 summarize the mean ADC1000, ADC2000, and ADCratio of the focal enhancing lesion vs the deep cervical muscles of the 2 groups. The mean ADC1000 in the recurrent tumor group was significantly lower than that in the posttreatment change group (1.205 vs 1.649 × 10⁻³ mm²/s, respectively; P < .001). Similarly, the mean ADC2000 also showed a lower value in the recurrent tumor group vs the posttreatment changes group, but without a statistically significant difference (0.878 vs 0.940 × 10⁻³ mm²/s; P = .365). The mean ADCratio of the recurrent tu-
The mean ADC ratio of recurrent tumor was significantly higher than that of the posttreatment changes group (73.5% vs 56.9%; \( P < .001 \)). No significant difference was observed between the recurrent tumor group and the posttreatment changes group in the mean ADC1000, ADC2000, and ADC ratio of the deep cervical muscles (Table 2).

However, the mean ADC ratio of enhancing lesion because of post-treatment changes was not significantly different from that of deep cervical muscles (56.9% vs 55.2%; \( P = .553 \)). Figure 2 shows representative MR images of the recurrent tumor group and the posttreatment changes group, respectively.

**Multivariate Logistic Regression Analysis**
The ADC1000 and ADC ratio were significantly different variables to differentiate between recurrent tumor and posttreatment changes by the independent Student \( t \) test. Multivariate logistic
regression analysis with the ADC_{1000} and ADC_{ratio} as independent variables was constructed. The ADC_{ratio} was the most independently differentiating variable ($P = 0.024$), whereas the ADC_{1000} was marginally insignificant ($P = 0.051$).

**Optimal Cutoff Values and Diagnostic Performances**

Receiving operating characteristic curves were drawn to find the optimal cutoff values for the ADC_{1000} and ADC_{ratio}. The optimal cutoff value for the ADC_{1000} was $1.460 \times 10^{-3}$ mm$^2$/s. The sensitivity, specificity, and accuracy were $85.0\%$ (17/20), $84.6\%$ (11/13), and $84.8\%$ (28/33), respectively. For the ADC_{ratio}, the optimal cutoff value was $62.6\%$, and the sensitivity, specificity, and accuracy were $95.0\%$ (19/20), $69.2\%$ (9/13), and $84.8\%$ (28/33), respectively. The summary of the diagnostic performance of each value is listed in Table 3.

**DISCUSSION**

Our results demonstrate that the ADC value derived from the standard b-value DWI ($b=1000$ s/mm$^2$) had a similar diagnostic performance compared with a previous study, and that the mean ADC_{1000} in the posttreatment changes group was significantly higher than that of the recurrent tumor group.\(^{13}\) The optimal cutoff value for the ADC_{1000} to distinguish between recurrent tumor and postoperative changes ($1.460 \times 10^{-3}$ mm$^2$/s) also correlated with a previous study ($1.30 \times 10^{-3}$ mm$^2$/s).\(^{13}\) These reproducible findings support the use of the standard b-value DWI on posttreatment follow-up imaging of HNSCC. On the other hand, the mean ADC_{1000} itself was not significantly different between the 2 groups and did not have an additional diagnostic benefit. However, we did observe a significant difference in the mean ADC_{ratio} between the recurrent tumor group and the posttreatment changes group (73.5 ± 7.2\% vs 56.9 ± 8.8\%, respectively); multivariate logistic regression analysis showed that the ADC_{ratio} vs the ADC_{1000} was more useful for differentiating between the 2 groups.

The ADC value has been known to decrease when the b-value increases beyond 1000 s/mm$^2$, according to several previous reports.\(^{20-22}\) The decrease in the observed ADC with an increasing b-value could be explained by the decay of biexponential signal intensity. In a human brain model, fast and slow diffusion components have been described.\(^{20,22}\) Fast diffusion components are the main source of signal at a relatively low b-value, whereas the signal intensity is dominated by the slow diffusion component at a high b-value.\(^{24}\) Increased cellularity in recurrent tumor leads to an increase in the intracellular water component, whereas posttreatment changes are composed of edema and inflammatory changes, increasing the proportion of easily diffusible extracellular water content.\(^{13}\) Although the intracellular and extracellular water components are not exactly equal to the slow and fast diffusion components, respectively, they are considered corresponding components.\(^{20,24}\) To evaluate the fast and slow diffusion components, DWI with multiple b-values has been studied with a biexponential fitting.\(^{25}\) In our study, we calculated 2 ADC values with a monoeponential model with 2 different b-values, and we adopted the ADC_{ratio} as an alternative biomarker that represents the composition of the fast and slow diffusion components. Choi et al\(^{18}\) hypothesized that by increasing the b-value from 1000 s/mm$^2$ to 2000 s/mm$^2$, the ADC value would have a more substantial decrease in the fast diffusion component. As a result, the higher ADC_{ratio} means that it contains more of the slow diffusion component and represents higher cellularity.\(^{18}\) Therefore, our results show that the mean ADC_{ratio} was much higher in the recurrent tumor group vs the posttreatment changes group.

Although the mean ADC_{2000} also showed a lower value in the recurrent tumor compared with posttreatment changes, it was not statistically different between the 2 groups. A possible explanation is that the relative decrease of ADC_{1000} to ADC_{2000} was higher in the posttreatment changes group; therefore, the final ADC_{2000} of the recurrent tumor group was similar to that of the posttreatment changes group. The differences between the ADC_{1000} and ADC_{2000} also could be influenced by different imaging parameters. However, Ogura et al\(^{26}\) reported that a long TR (> 6000 ms) and short TE (< 100 ms) did not significantly influence the ADC values. Therefore, the influence of different imaging parameters was thought to be negligible in our study.

For comparison, we also investigated the ADC values from the deep cervical muscles as a normal soft tissue. With the increase in the b-value from 1000 to 2000 s/mm$^2$, the ADC value was also substantially decreased in muscle. The mean ADC ratio of the recurrent tumor group was significantly higher than that of the deep cervical muscles, which might prove beneficial for the detection of recurrent tumor by visual inspection in the ADC_{ratio} maps.

The diagnostic yields of both ADC_{ratio} and ADC_{1000} in our present study was lower than those of the study by Abdel Razek et al,\(^{13}\) in which they used only ADC_{1000} maps. We believe that this finding might be the result of differences in study populations. The minimal size of the lesions was 1.5 cm in diameter in the study by Abdel Razek et al,\(^{13}\) whereas our study included smaller lesions (eg, 5 mm).

In our study, 15 patients were excluded because of MR imaging artifacts or poor visualization of the lesion, and the proportion of artifacts in eligible patients was relatively high (26.8\%). Although we optimized scanning parameters to reduce artifacts and maximize the signal-to-noise ratio, we found that the intrinsic limitations of single-shot echo-planar DWI in head and neck imaging (eg, heterogeneity of the tissue, a very low acquirable signal, movements, air-tissue boundaries, and surgical materials) were still challenging in interpreting the DWI.\(^{27}\) To overcome the drawbacks of DWI, additional localized coverage imaging or zonally magnified oblique multisection (ZOOM; Siemens, Erlangen, Germany) echo-planar imaging could be performed.\(^{28}\)

Our study had some limitations. One limitation was that we enrolled a small number of patients from a single center and performed retrospective analysis, which could lead to selection bias.
We tried to include all patients who met the inclusion criteria to minimize selection bias. In addition, we included HNSCC with various locations, treatment modalities, and intervals between last treatment and imaging, and this heterogeneity could limit the generalizability of our results. Although tumor location is related to prognosis, we believed that any significant impact of tumor location relative to ADC values was unlikely.

Another limitation of our present study was that there were patients for whom we did not have histopathologic confirmation. Therefore, exact correlation of the ADC value or ADC\textsubscript{ratio} with histopathologic changes was limited, especially for the posttreatment changes group. In clinical settings, it is common practice to follow patients with complementary imaging modalities, such as FDG-PET, to ensure that the enhancing lesion identified by MR imaging is metabolically active before a biopsy is performed, but this was not possible in the context of our study.

CONCLUSIONS

We suggest that the ADC\textsubscript{ratio}, calculated from ADC\textsubscript{1000} and ADC\textsubscript{2000} is a promising value to differentiate between recurrent tumor and posttreatment changes in HNSCC and may be marginally more useful than the ADC\textsubscript{1000} alone. High b-value DWI of the head and neck region is technically feasible and requires a relatively short additional scan time; therefore, high b-value DWI could be added to the posttreatment routine follow-up MR imaging to provide additional potentially helpful information in the detection of recurrent HNSCC.
