ABSTRACT

BACKGROUND AND PURPOSE: Decreased oxygen supply may cause neuronal damage in the brains of patients with COPD, which is manifested by clinical symptoms such as neuropsychological deficits and mood disorders. The aim of the present study was to investigate brain gray matter change in COPD.

MATERIALS AND METHODS: Using voxel-based morphometry based on the high-resolution 3D T1-weighted MR images of GM volume, we investigated 25 stable patients with COPD and 25 matching healthy volunteers. A battery of neuropsychological tests was also performed.

RESULTS: Patients with COPD (versus controls) showed reduced GM volume in the frontal cortex (bilateral gyrus rectus, bilateral orbital and inferior triangular gyri, and left medial superior gyrus), right anterior insula, cingulate cortex (left anterior and middle gyri, right middle gyrus), right thalamus/pulvinar, right caudate, right putamen, right parahippocampus, and left amygdala. In COPD, in some of these regions, regional GM volume had positive correlations with arterial blood pO2, while in some regions, regional GM volume had negative correlations with disease duration. Patients with COPD (versus controls) had poorer performance in the Mini-Mental State Examination, Visual Reproduction, and Figure Memory tests. Moreover, the GM volume in the inferior triangular frontal cortex in patients with COPD was significantly correlated with the Picture Memory score.

CONCLUSIONS: Our findings suggest GM reductions in a number of brain regions in COPD, which were associated with disease severity and may underlie the pathophysiologic and psychological changes in patients with COPD.

ABBREVIATIONS: COPD = chronic obstructive pulmonary disease; DARTEL = Diffeomorphic Anatomical Registration Through Exponentiated Lie algebra; FEV = forced expiratory volume; FVC = forced vital capacity; GM = gray matter; SaO2 = arterial oxyhemoglobin saturation

COPD continues to be a major cause of death,1 The irreversible airflow limitation characteristic of COPD is usually progressive, which could subsequently cause decreased oxygen supply to the brain. Because the brain is extremely sensitive to changes in arterial oxygen concentration,2 it inevitably has hypoxic stress. In addition, patients with COPD often have systemic inflammation,1 which may exacerbate neuronal injury. In fact, neuronal damage in the brains of patients has been manifested in clinical symptoms such as neuropsychological deficits,2-6 depression and anxiety,1,7 and physical disabilities.1 Deterioration in cerebral perfusion8 and a decrease in cerebral metabolites9-12 have also been reported. All the above characteristics of COPD suggest the presence of brain structure alteration. However, until now, it remains largely uninvestigated, to our knowledge.

In this study, voxel-based morphometry based on 3D T1-weighted MR imaging, was used to measure GM volume in patients with COPD. Recently, the preprocessing steps of voxel-based morphometry have been improved with the DARTEL registration method. The DARTEL algorithm uses a more sophisticated mathematical framework and achieves sharper nonlinear registration than parametric approaches, which exponentiates a velocity field to produce deformations. A “diffeomorphism” is a globally one-to-one (objective) smooth and continuous mapping with derivatives that are invertible. This is an important advance for transformation to best represent the normalization of a brain image to an appropriate template. Therefore, instead of as previously simply matching a pair of images, DARTEL can achieve accurate realignment of small inner structures. Voxel-based morphometry DARTEL has been widely applied in clinical studies.

Functional MR imaging studies on breathlessness, air hunger, and inspiratory-loaded breathing have revealed that a large number of brain regions, including the frontal cortices, temporal cortices, limbic/paralimbic cortices, cerebellum, and midbrain, are activated by dyspnea. Moreover, these dyspnea-activated brain regions have also been shown to be impaired in patients with long-term sustained hypoxia exposure, such as patients with congenital central hypoventilation syndrome; those with long-term intermittent hypoxia exposure, such as obstructive sleep apnea; and high-altitude residents. Dyspnea is the most common and disabling symptom in patients with COPD. We therefore hypothesized that patients with COPD would have similar cerebral impairment.

**MATERIALS AND METHODS**

**Subjects**

Twenty-five patients were enrolled from December 2009 to May 2011. All patients had undergone a period of 30–45 days of in-hospital rehabilitation following an acute exacerbation of COPD. At the time of data collection, patients were in a stable condition. Among these patients, 12 discharged patients were recruited during their rest at home and 13 patients were recruited when they were awaiting discharge from the hospital. Patients were diagnosed in Zhongshan Hospital (Xiamen, China) according to the diagnostic criteria of the Global Initiative for Chronic Obstructive Lung Disease. Twenty-five healthy volunteers, with comparable age, sex, and educational background, composed the control group. All subjects were free from a known history of cerebrovascular accident, heart failure, neurologic disorders, obstructive sleep apnea, or other diseases known to affect cognition. Patients were provided with therapy, including inhaled ipratropium bromide, bricanyl, albuterol (Ventolin), and budesonide. Demographic characteristics of the patients and healthy volunteers are listed in Table 1. All subjects provided written informed consent. The experimental protocol was approved by the Research Ethics Review Board of Xiamen University.

**Physiologic and Neuropsychological Tests**

Physiologic and neuropsychological tests and assessment of activities of daily living (score range, 14–56) were conducted 1 day before the MR imaging. Physiologic tests included pulse rate and arterial blood pressure measures, arterial blood gas analysis, and pulmonary function measures. Blood samples were taken in the morning between 7:00 and 7:30. The neuropsychological tests included the following: 1) the Chinese version of the Mini-Mental State Examination, which measures general cognitive function; and 2) the Visual Reproduction Test, Figure Memory Test, and Digit Span Forward and Backward Tasks, which, taken from the Chinese revised version of the Wechsler Memory Scale, were used to measure visuoconstructive ability, visuospatial memory, short-term verbal memory, and working memory, respectively. All data were analyzed by using the Statistical Package for the Social Sciences, Version 19.0 (SPSS, Chicago, Illinois). An independent t test measured between-group differences. Statistical significance was set at P < .05.

**MR Imaging Data Acquisition**

Images were acquired on a Tim Trio 3T scanner (Siemens, Erlangen, Germany) at the MR Imaging Center (Zhongshan Hospital, Xiamen, China). 3D structural MR imaging was performed in each subject by using a T1-weighted magnetization-prepared rapid acquisition of gradient echo sequence (TR/TE = 1900/2.48 ms, FOV = 25 × 25 cm², NEX = 1, matrix = 512 × 256, section thickness = 1.0 mm). Conventional 2D T1 and T2 images were also acquired and examined for any incidental findings. The data analysis was conducted by 2 researchers who were blinded to the status of subjects.

**Voxel-Based Morphometry Analysis**

Data were analyzed by using the VBM8 toolbox implemented in SPM8 (Wellcome Department of Imaging Neuroscience, University College London, London, UK). Calculations and image matrix manipulations were performed by using Matlab (MathWorks, Natick, Massachusetts). The processes included the following steps: 1) the images were inspected for artifacts and set at the anterior commissure. Using the unified segmentation procedure, we segmented the reoriented image into GM, white matter, and CSF in the same space as the original T1-weighted image. Procrustes-aligned GM images were generated by a rigid-body transformation, which used isomorphic scaling, translation, and rotation to find the “best” fit between ≥2 landmarked shapes. 2) The DARTEL registration method, which is implemented in SPM8, was used to create a study-specific template by using the aligned images from all patients and controls to improve intersubject registration of structural images. The procedure involved 6 iterations, which began with creating an initial tem-
plate from all the aligned images, and was followed by the registration on each of the subjects in turn. Then, the first iteration of the registration was completed in each subject, and a new template was created. After this, the second iteration began. When 6 iterations of averaging and registration were finished, the final template was generated, which was the average of the DARTEL registered data. During iterations, all images were warped to the template, yielding a series of flow fields that parameterized deformations to use in modulations to preserve actual GM volume. The GM images were modulated to account for the local compression and stretching that occurs as a consequence of the warping and affine transformation, which is based on the change of variables theorem. 3) The normalized images were transformed into Montreal Neurological Institute space. These GM images were then smoothed by using a Gaussian kernel of 8-mm full width at half maximum. Independent t tests were performed to examine between-group differences. The statistical parametric map was generated with the voxel level threshold at \( t > 3.7473, P < .05 \) (false discovery rate correction with sex, age, and education as covariates). False discovery rate correction was used because it focuses on the proportion of rejections that are false. It is less conservative and easy to interpret, and it offers an objective and data-driven perspective for threshold statistical maps.\(^2\,^3\)

To analyze the correlation of GM image values with cognitive or physiologic measurement, we took the following steps: 1) Regions of interest were created for clusters showing differences between groups, and 2) by using these region-of-interest masks, the GM values were extracted from each individual’s normalized and smoothed GM maps. Then the partial correlations were analyzed by using SPSS. Statistical significance was set at \( P < .05 \), with sex, age, and education as covariates.

### RESULTS

**Physiologic and Behavioral Findings**

Compared with the controls, patients with COPD had markedly lower arterial blood SaO₂ and pO₂ values and higher arterial blood pCO₂ values and heart rates (Table 2). Patients with COPD had markedly lower 1-second FVC, FEV₁, and FEV₁/FVC values and higher respiratory rates. Patients with COPD had markedly lower scores in the activities of daily life, the Mini-Mental State Examination, and Visual Reproduction, and Figure Memory tests.

### Regional GM Volume

No subject from either group showed visible abnormalities on T1-weighted structural images. Voxel-based morphometry analysis showed that patients with COPD had reduced regional GM volumes compared with healthy controls in the frontal cortex (bilateral gyrus rectus, bilateral orbital gyrus, bilateral inferior triangular gyrus, and left medial superior gyrus), right anterior insula, cingulate cortex (left anterior and middle gyri, right middle gyrus), right thalamus/pulvinar, right caudate, right putamen, right parahippocampus, and left amygdala (cluster size, >70 voxels) (Figs 1–4).

### Correlations

In patients with COPD, partial correlation (controlling for disease duration, FEV₁/FVC, and age) revealed that GM volume in the gyrus rectus \( (r = 0.531, P = .017) \), right frontal inferior orbital gyrus \( (r = 0.496, P = .025) \), left frontal superior orbital gyrus \( (r = 0.459, P = .037) \), right insula \( (r = 0.564, P = .012) \), right middle cingulate gyrus \( (r = 0.490, P = .027) \), right thalamus/pulvinar \( (r = 0.746, P < .001) \), and left amygdala \( (r = 0.471, P = .033) \) had positive correlations with arterial blood pO₂ values. Partial corre-
lation (controlling for pO2, FEV1/FVC, and age) revealed that GM volume in the right frontal inferior orbital gyrus ($r = 0.463$, $P = .015$), right inferior triangular gyrus ($r = 0.436$, $P = .021$), left medial superior frontal gyrus ($r = 0.417$, $P = .027$), right insula ($r = 0.623$, $P = .001$), and right parahippocampal gyrus ($r = 0.564$, $P = .003$) had negative correlations with disease duration. GM volume in the right inferior triangular frontal gyrus in patients with COPD correlated significantly with the Picture Memory score ($r = 0.475$, $P = .019$).

**DISCUSSION**

Decreased oxygen supply, resulting from the irreversible airflow limitation, may cause neuronal damage in the brains of patients with COPD. Our present study revealed that patients with COPD had reduced GM volume in a number of brain regions, which were mainly confined to the limbic/paralimbic structures and frontal cortices, compared with healthy controls. These findings are consistent with those in patients with obstructive sleep apnea, congenital central hypoventilation syndrome, and pediatric heart failure, and in high-altitude residents. Moreover, patients with COPD exhibited poorer performance on visuospatial and visual reproduction tasks.

GM volume in the reduced regions in patients with COPD had a strongly positive correlation with arterial blood pO2 values, which suggested that the reduced GM may result from sustained low blood oxygen. Hypoxia-induced metabolic decreases and cerebral perfusion decline in COPD may be the cause of morphologic reductions. In addition, systemic inflammation in COPD can exacerbate neuronal injury. A greater proportion of regions showing GM loss located in the limbic/paralimbic cortices in patients with COPD found in the present study may be due to the fact that those phylogenetically older regions of the brain showed sharper vascular responses to hypoxia than evolutionarily younger regions. Although there is evidence that cigarette smoking may cause neuronal damage in the brains of patients with COPD, nicotine has no selective effect on some brain regions.

Various studies have suggested that the unpleasantness of subjectively perceived dyspnea was processed in distinct brain areas. However, neuroimaging studies have suggested that the right anterior insula seemed to be the most consistent structure across studies. Therefore, we speculated that the reduction in the right anterior insular GM would have reduced the perception of dyspnea in patients with COPD. The finding that patients with insula lesions exhibit a decrease in unpleasant pain, sharpness, and thermal sensation may support our assumption. In addition, mor-
The GM volume in the right inferior triangular frontal gyrus has a positive correlation with the Picture Memory score, suggesting that it may be responsible for the deficits in visuospatial tasks. Previous studies have suggested that the right inferior frontal cortex processes emotional communicative information with visual input during the observation and execution of actions. The reduced GM volume in the anterior insular cortex, anterior cingulate cortex, and pulvinar may contribute to the deficits in visuoconstructive tasks. Our assumption was based on the following previous data: 1) Visual stimuli activated the network comprising the anterior insular cortex, anterior cingulate cortex, and prefrontal cortex, and 2) the pulvinar has connections to the visual areas and to the frontal and parietal oculomotor cortices and has been implicated in various visual functions in lesion studies.

CONCLUSIONS

We first demonstrated that COPD extended to the brain, with the reduction of regional GM volume in a number of brain regions. Our findings suggest significant participation of these structures in responding to hypoxic challenges, which include cardiovascular and air-hunger components. The brain structural changes may also underlie the psychological and mood changes in patients with COPD.
