Mechanical Thrombectomy Using the New ERIC Retrieval Device Is Feasible, Efficient, and Safe in Acute Ischemic Stroke: A Swiss Stroke Center Experience

ABSTRACT

BACKGROUND AND PURPOSE: Intravenous thrombolysis and mechanical thrombectomy predominantly using stent retrievers have been shown to effectively restore cerebral blood flow and improve functional outcome in patients with acute ischemic stroke. We sought to determine the safety and feasibility of mechanical thrombectomy using the new ERIC retrieval device.

MATERIALS AND METHODS: We identified 36 consecutive patients from our Stroke Center registry with acute ischemic stroke who were treated with the new ERIC retriever from September 2013 to December 2014. Patients with ischemic stroke meeting the following criteria were eligible: onset-to-treatment time of ≤4.5 hours or wake-up stroke (n = 10) with relevant CT perfusion mismatch, NIHSS score of ≥4, and proof of large-vessel occlusion in the anterior circulation on CT angiography. We assessed the baseline characteristics including age, sex, comorbidities, stroke severity, site of vessel occlusion, presence of tissue at risk, and treatment-related parameters such as onset-to-treatment time, recanalization grade, and outcome.

RESULTS: The mean age was 70 ± 13 years, and the median NIHSS score on admission was 18 (interquartile range, 10–20). Seventeen of 36 patients were on platelet inhibitors or anticoagulants before endovascular treatment (47.2%); 20 patients received intravenous thrombolysis (55.5%). The ERIC was used as the sole retriever in 28 patients (77.8%) and as a rescue device in 8. Excellent recanalization was achieved in 30/36 patients (83.3%) with TICI 3 in 19/36 and 2b in 11/36, respectively. Median procedural time in these patients was 90 minutes (interquartile range, 58–133 minutes). No intra-procedural complications occurred.

CONCLUSIONS: In this observational study, the new ERIC retrieval device was technically feasible, safe, and effective in acute ischemic stroke with large-vessel occlusion.

ABBREVIATIONS: ERIC = Embolus Retriever with Interlinked Cages; IQR = interquartile range; IVT = intravenous thrombolysis; sICH = symptomatic intracerebral hemorrhage

Early restoration of cerebral blood flow is crucial to prevent persistent brain damage in acute ischemic stroke. Intravenous thrombolysis (IVT) with tPA has been shown to increase recanalization rates¹ and improve clinical outcome within 4.5 hours after symptom onset.²,³ Still, its effectiveness in large-vessel occlusion is rather limited.⁴ In contrast, endovascular interventions, in particular mechanical thrombectomy, have revealed high rates of recanalization in proximal artery occlusion (reviewed by Jansen and Rohr⁵). In the past decade, various devices have been introduced for this purpose (reviewed by Spiotta et al⁶). Just recently, new-generation stent retrievers were launched and proved to be even more effective than previous approaches.⁷–⁹

However, even the latest devices need to be deployed for several minutes before retrieving the thrombus and thus require precious time. Moreover, 1 device does not fit all occlusion types, and alternative effective devices are warranted. In this pilot study, we sought to determine the feasibility, efficacy, and safety of mechanical thrombectomy in patients with acute ischemic stroke by using the new Embolus Retriever with Interlinked Cages (ERIC; MicroVention, Tustin, California) (Fig 1B).

MATERIALS AND METHODS

Patients

We identified 36 consecutive patients with acute stroke who were treated with the new ERIC device from September 2013 to December 2014 at the Cantonal Hospital Aarau Stroke Center. Ethical approval was obtained from the local ethics committee.

Patients with ischemic stroke were eligible if they met the fol-
lowing criteria: 18 years of age or older; onset-to-treatment

time of 4.5 hours or wake-up-stroke with relevant CT perfu-
sion mismatch, NIHSS score of 4, and proof of large-vessel

occlusion in anterior circulation arteries (ICA, MCA, anterior
cerebral artery) on CT angiography. As mentioned above, pa-
tients with unknown onset of symptoms (wake-up stroke) un-
derwent a CTP series, which included a time-to-peak map with

a threshold of 6 seconds and a cerebral blood volume map. A

TTP/CBV area ratio of 2 was considered a relevant CTP

mismatch.

IVT with 0.9 mg/kg of body weight was started immediately in
eligible patients in-house or at the referring hospital if applicable.

Intra-arterial urokinase (1.000.000 IU/60 minutes) was used in

certain cases at the treating physician’s discretion (n = 2). The

new ERIC is formed by 3–5 interlinked cages with diame-
ters ranging from 3 to 6 mm and a resulting working length of

15–44 mm (Fig 1). Thus, the number of working cages can be

adjusted to the required working length. The ERIC is designed
to retract the clot coaxially and prevent the captured clot from

shearing off during retraction. All procedures were performed

on an Allura Xper FD20/20 biplane angiography system

(Philips Healthcare, Best, the Netherlands) according to the
departmental protocol with intraprocedural modification if

required. Briefly, an 8F balloon-guide catheter was placed in

the distal common carotid artery. A heparinized saline solu-
tion was continuously perfused through the catheter during the

procedure. With the balloon of the guide catheter deflated, a 0.0014-inch guidewire was advanced coaxially over a Head-

way 17 Advanced Microcatheter (MicroVention) within the oc-
ccluded intracranial vessel and navigated distal to the clot. The Headway 17 microcatheter was then advanced over the wire

Outcome Measures

We assessed treatment-related parameters such as onset-to-treatment time (last seen normal to groin puncture), procedural time (groin puncture to final recanalization), recanalization grade (Thrombolysis in Cerebral Infarction score), intra-/postprocedural complications (eg, symptomatic intracerebral hemorrhage [sICH]), and functional outcome at discharge (NIHSS/mRS) and at 3 months (mRS).

Recanalization was defined as being “satisfactory” with TICI 2–3 and “excellent” with TICI 2b/3. Intraprocedural complications included vessel dissection or perforation, embolic events in previously unaffected territories, or sICH during the procedure. Intraprocedural symptomatic intracerebral hemorrhage was defined as proof of intracerebral hemorrhage on final tomography in the angiography suite and a decline in the NIHSS score of ≥4 points. Functional outcome at 3 months was considered “favorable” with an mRS of ≤2 (independent) and “satisfactory” with an mRS of ≤3 (ambulatory without help).

Endovascular Procedure

Following criteria: 18 years of age or older; onset-to-treatment time of ≤4.5 hours or wake-up-stroke with relevant CT perfusion mismatch, NIHSS score of ≥4, and proof of large-vessel occlusion in anterior circulation arteries (ICA, MCA, anterior cerebral artery) on CT angiography. As mentioned above, patients with unknown onset of symptoms (wake-up stroke) underwent a CTP series, which included a time-to-peak map with a threshold of ≥6 seconds and a cerebral blood volume map. A TTP/CBV area ratio of ≥2 was considered a relevant CTP mismatch.

IVT with 0.9 mg/kg of body weight was started immediately in eligible patients in-house or at the referring hospital if applicable. Intra-arterial urokinase (1,000,000 IU/60 minutes) was used in certain cases at the treating physician’s discretion (n = 2).

We determined baseline characteristics, including age, sex, co-morbidities, cardiovascular risk factors, previous medication, stroke severity, and site of vessel occlusion (Table 1).
through the clot and the guidewire was exchanged for the embolectomy device. The ERIC was advanced and deployed a few millimeters distal to the clot. The balloon of the guide catheter was inflated, and the microcatheter and the embolectomy device were gently withdrawn under continuous proximal aspiration with a syringe. A control angiography was performed to confirm recanalization and reperfusion. Modifications of the standard procedure are reported in On-line Table 1.

RESULTS
Baseline Data
Patient baseline characteristics are presented in detail in Table 1. The mean age was 70 ± 13 years, and 47.2% were female patients. The median NIHSS score on admission was 18 (interquartile range [IQR], 10–20). Twenty-five patients had hypertension, 16 had hypercholesterolemia, and 5 had diabetes mellitus, and 9 were active cigarette smokers. In addition, the modified Charlson Index as a measure of comorbidities showed a light-to-moderate burden with a median modified Charlson Index of 1 (IQR, 0–2). Strokes of 36 patients were considered wake-up with undetermined onset of symptoms.

Procedural Data
CT angiography on admission revealed the following occlusion types: MCA M1 segment (n = 19), MCA M2 segment (n = 9), terminal carotid-T (n = 4), tandem (intracranial internal carotid artery bifurcation–MCA, n = 3), and combined MCA M1 and anterior cerebral artery (n = 1) (Table 1).

In 20 patients, intravenous tPA was started before mechanical thrombectomy. Intra-arterial urokinase was administered in another 2 patients without prior intravenous thrombolytic therapy. ERIC was used as the single retriever in 28 patients (77.8%) and as a rescue device in 8. Excellent recanalization was achieved in 30 of 36 patients (83.3%) with TICI 3 in 19/36 and 2b in 11/36, respectively. Median procedural time was 90 minutes (IQR, 58–133 minutes) in these patients. General anesthesia was required in 13/36 patients, whereas 23/36 procedures were performed with the patient under conscious sedation. No intraprocedural switch from conscious sedation to general anesthesia was necessary, and no intraprocedural complications occurred. The median time from symptom onset to groin puncture was 4 hours 57 minutes (IQR, 3 hours 36 minutes to 7 hours 47 minutes).

Clinical Outcome
The median NIHSS score at discharge was 9 (IQR, 2–16), corresponding to a decrease of 9 points compared with the median NIHSS score on admission (Table 2). One-third of patients achieved favorable outcome (mRS ≤2) at 90 days after the ischemic event. Satisfactory outcome (mRS ≤3) was achieved in 14/36 when leaving the hospital, with an increase to 21/36 (58%) 3 months later.

Three sICHs (8.3%) were documented in the early course of hospitalization, all in patients with successful recanalization. No intraprocedural intracerebral hemorrhage occurred.

There was a 19.4% in-hospital mortality (7/36) due to the development of fulminant cerebral edema despite successful recanalization in 3 patients (all TICI 3), followed by decompressive surgery in 2 of them and sICH in 1 of the latter. A fourth patient had vessel reocclusion on the same day after incomplete recanalization (TICI 2a) and developed a large MCA infarct. Because of considerable pre-stroke comorbidities with metastatic lung cancer and multiple myeloma, the latter patient’s relatives and the treating physicians agreed to not extend diagnostic and therapeutic procedures according to the patient’s presumed decision, with death on day 3. Accordingly, 3 patients with severe systemic infections (pneumonia in 2 and unidentified focus in 1) during hospitalization were continued on palliative care due to severe neurologic deficits, advanced age, and the poor prognosis. No intraprocedural deaths occurred.

During the 3-month follow-up, mortality further increased to 27.8% (10/36). One patient died 54 days after stroke during rehabilitation, with bacterial pneumonia and septicemia resulting in multiorgan failure. In the other 2 patients, therapeutic procedures were terminated in agreement with the patient’s relatives and the patient’s presumed decision due to age, stroke severity, and fatal prognosis.

One patient (patient 29, On-line Table 1) with successful recanalization and considerable clinical benefit, with an improvement from NIHSS 19 on admission to NIHSS 2 (and mRS 3) at discharge, underwent aortic arch replacement due to an incidental aortic arch aneurysm 10 weeks later. Perioperatively, he developed new focal neurologic deficits with proof of new ischemic infarcts on cranial CT, resulting in an mRS score of 5 at 3-month follow-up.

DISCUSSION
Retrieving thrombi with the new ERIC device was technically feasible, effective, and safe in this pilot study of acute ischemic stroke with large-vessel occlusion in anterior circulation arteries. The ERIC is designed to adapt to different vessel diameters and thrombus lengths and is thus available in diameters ranging from 3 to 6 mm and a working length of 15–44 mm with 3–5 spheres. The minimal required microcatheter internal diameter is 0.017 inches for all ERIC types. Proximal vessel occlusions, such as carotid-T occlusions, could be reached as easily as M2 branch occlusions in this pilot study.

Satisfactory recanalization with TICI grades 2–3 was demonstrated in 94.4%, being excellent in 83.3% (TICI 2b–3). Additional thrombus aspiration at the end of the procedure further enhanced recanalization efficacy in 1 patient (patient 8). These high rates of successful recanalization also resulted in a substantial proportion of patients with an independent outcome (mRS ≤2, 33.3%). Of note, as many as 21 patients were ambulatory without help (mRS ≤3, 58.3%) 3 months after the index event. These findings are in line with the recently published Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands (MR CLEAN) trial, predominantly using the Solitaire stent retriever (Covidien, Irvine, California) (mRS 2, 33%; mRS 3, 51%), and they are close to the results of the Spanish multicenter Endovascular Revascularization with Solitaire Device versus Best Medical Therapy in Anterior Circulation Stroke within 8 Hours (REVASCAT) trial (mRS 2, 44%; mRS 3, 62%). The higher rates of favorable functional outcome in the Endovascular Treatment for Small Core and Anterior
Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times (ESCAPE) trial,13 Extending the Time for Thrombolysis in Emergency Neurological Deficits—Intra-Arterial (EXTEND-IA) trial,11 and Solitaire With the Intention For Thrombectomy as PRIMary Endovascular Treatment (SWIFT PRIME) trial15 are most likely attributable to a shorter time from stroke onset to mechanical thrombectomy (difference median, >60 minutes).

Overall, the median NIHSS score decreased from 18 points on admission to 9 points at discharge. The median NIHSS score on admission was 20 (range, 16–27) in patients who died during the 3-month follow-up period compared with 15 points (range, 5–21) in survivors. A high NIHSS score on admission is a known predictor of poor outcome,16 and despite the small numbers currently studied, our data further support this finding. Less than one-third of patients (10/36) died before the end of the 3-month follow-up period. None of those deaths could be directly attributed to the endovascular procedure or the retrieval device. The fulminant development of cerebral edema with or without sICH during hospitalization and the consequences of stroke severity and advanced age during follow-up explained the reported deaths. Moreover, the mortality rate was in line with previously published data of mechanical thrombectomy studies by using the Merci retriever (Concentric Medical, Mountain View, California), Penumbra System (Penumbra, Alameda, California), Revive device (Codman Neurovascular, Raynham, Massachusetts), or Trevo device (Stryker, Kalamazoo, Michigan), and it tended to slightly exceed mortality rates reported in many trials using the Solitaire stent retriever (compare On-line Table 2). However, until recently, these trials lacked power and were not designed to show the superiority of one device or the other. In particular, the study designs were very heterogeneous among those trials; small numbers were studied in most of the trials; and regarding the present observational single-arm study, more than one-third of the patients were treated in an extended time window, even beyond 6 hours from symptom onset based on CT mismatch.

In fact, given the promising results in terms of favorable and satisfactory outcome with the new ERIC retrieval device (mRS ≤2, 33.3%; mRS ≤3, 58.3% at 90 days), even in the light of a comparatively longer onset-to-treatment time by using advanced imaging protocols, the new ERIC adds a great asset to the existing armamentarium of recanalization devices. In addition, it further encourages research dealing with the use of advanced imaging techniques for patient selection.

Also in terms of safety, the ERIC appeared to be reliable and was free of intraprocedural complications. The rate of sICH (8.3%) during hospitalization was comparable with that in previously reported trials using mechanical thrombectomy devices (On-line Table 2). Most interesting, all 3 sICHs in our pilot study occurred after the intervention and were associated with intravenous thrombolysis, successful recanalization, massive edema formation, and the need for decompressive surgery, indicating a common mechanism with underlying blood-brain barrier disruption.

Conscious sedation was chosen if possible. General anesthesia was required in 13/36 patients due to persisting vomiting, agitation, or impaired consciousness. However, the best anesthesiology management in endovascular stroke therapy is not known to date and is being investigated in a large randomized controlled trial (https://www.clinicaltrials.gov/; Sedation vs. Intubation for Endovascular Stroke TreAtment [SIESTA], NCT 02126085).

Our pilot study certainly has some limitations: the retrospective monocenter single-arm design, a rather small number of patients, and the lack of formally independent assessment of TICI score and procedural complications. Thus, the results should be interpreted with caution.

However, to our knowledge, this is the first report on consecutive patients with stroke treated with the new ERIC retrieval device. Our findings support the safety and effectiveness of mechanical thrombectomy in terms of vessel recanalization and show a clinical benefit. Moreover, despite the rather extended period from stroke onset to intervention and the lower rate of IVT, our results are promising and in line with previously published data by using other recanalization devices with a shorter time to treatment and higher rates of IVT.

After the stunning results of the Interventional Management of Stroke (IMS) III trial, SYNTHESIS expansion, and Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR RESCUE) trials,17-19 showing no benefit of endovascular treatment compared with standard care including IVT, the news from the latest trials, ie, MR CLEAN,11 ESCAPE,13 EXTEND-IA,14 SWIFT PRIME,15 and REVASCAT,12 clearly demonstrated the safety and effectiveness of an intra-arterial approach for acute stroke treatment in selected patients within the first hours of symptom onset.

**CONCLUSIONS**

The new ERIC retrieval device appears to be technically safe and effective in removing thrombi in large-vessel occlusion. Moreover, despite substantial focal neurologic deficits on admission and an onset-to-treatment time of, on average, >6 hours (mean, 6 hours 13 minutes; median, 4 hours 57 minutes), almost one-third of patients achieved an independent functional outcome.
