**ABSTRACT**

**BACKGROUND AND PURPOSE:** The results of conventional core biopsy for some thyroid nodules with indeterminate cytology have still remained indeterminate. The aim of this study was to evaluate whether the ultrasonography-guided core needle biopsy technique containing the nodule, capsular portion, and surrounding parenchyma was more effective than a conventional method in enhancing diagnostic yield for circumscribed solid thyroid nodules without malignant sonographic features.

**MATERIALS AND METHODS:** This retrospective comparative study evaluated 26 thyroid nodules in 26 consecutive patients between 2006 and 2010. They were biopsied by using a conventional method, and 61 nodules from 60 patients were biopsied by using a modified ultrasonography-guided core needle biopsy technique in 2013. The patients enrolled in this study presented with circumscribed solid thyroid nodules without malignant sonographic features, classified as nondiagnostic or atypia/follicular lesions of undetermined significance at previous cytology. The ultrasonography-guided core needle biopsy results of the 2 groups were compared.

**RESULTS:** The rate of inconclusive ultrasonography-guided core needle biopsy results was 34.6% (9/26) in the conventional group and 11.4% (7/61) in the modified technique group (\(P = .018\)). There was no significant difference in the mean size of the nodules between the 2 groups (\(P = .134\)). The malignancy rate was 33% (3/9) for the conventional group and 52% (27/52) for the modified technique group (\(P = .473\)). The most common malignant pathology was a follicular variant of papillary thyroid carcinoma and follicular adenoma was the most common benign lesion.

**CONCLUSIONS:** For circumscribed solid nodules without malignant sonographic features with indeterminate cytology, the ultrasonography-guided core needle biopsy technique containing the nodule, capsular portion, and surrounding parenchyma is more effective in diagnostic yield compared with a conventional method that biopsies the intranodular portion.

**ABBREVIATIONS:** AUS/FLUS = atypia or follicular lesions of undetermined significance; CNB = core needle biopsy; FNA = ultrasonography-guided fine-needle aspiration; PTC = papillary thyroid carcinoma; US = ultrasonography.
another growth pattern) is distinct from that of the surrounding thyroid parenchyma. Nodular hyperplasia is one of the most common pathologies in benign thyroid disease and is characterized by a densely cellular follicular proliferation that lacks a capsule on histology. Because nodular hyperplasia may sometimes be considered normal thyroid tissue after core needle biopsy diagnosis, the presence of a capsule and normal parenchyma in the thyroid nodule can be meaningful for the differentiation of a follicular neoplasm from nodular hyperplasia. Nodules with circumscribed solid features only identified on US are diagnosed as indeterminate because they have neither malignant nor benign features. Moreover, indeterminate FNA of these lesions may lead to an unnecessary diagnostic operation. Thus, circumscribed solid thyroid nodules not associated with other malignant features require the use of CNB techniques under US guidance other than a conventional method that biopsies the internal portion of the thyroid nodule. One recent study suggested that the use of a CNB technique that biopsied the capsule of the thyroid nodule and the surrounding parenchyma was useful for the diagnosis of cytologically indeterminate nodules. However, the authors did not compare the results of the conventional method with those of the modified method or focus on the diagnosis of problematic nodules by using a conventional CNB method. We evaluated whether the modified CNB technique was more effective in the diagnostic yield of circumscribed solid nodules without malignant sonographic features with indeterminate cytology compared with a conventional method. Therefore, we compared the inconclusive rate (nondiagnostic or AUS/FLUS rate) and malignant rate of CNB results between the conventional and the modified technique groups.

MATERIALS AND METHODS

Study Design and Patients

This retrospective study was approved by the institutional review board of our institution, and the requirement for informed consent was waived. However, informed consent for procedures was obtained from patients before they underwent the ultrasonography-guided fine-needle aspiration and US-CNB procedures. From April 2006 to December 2010, US-CNB was performed on 109 patients with 109 thyroid lesions. Twenty-one patients were excluded because of the absence of a history of ultrasonography-guided fine-needle aspiration. The remaining 88 patients had inconclusive results on initial FNA readings obtained in our institution. Among them, 26 consecutive patients presented with 26 thyroid nodules, which were circumscribed solid nodules on US without typical malignant sonographic features (spiculated margins, microcalcifications, marked hypoechoogenicity, and taller-than-wide shape). Twenty-five patients from this study had been included in our prior study by Hahn et al.

Histologic Examination

Two or 3 specimen cores were fixed in formalin and entirely embedded in a paraffin block. Immunohistochemical staining was
performed when needed by pathologists. However, we did not assess the role of the immunohistochemical results for the contribution to the diagnosis. The diagnosis of CNB specimens was interpreted by 1 of 6 cytopathologists. One expert with 15 years of experience in thyroid cytopathology supervised the other cytopathologists in questionable cases. Histologic diagnosis on US-CNB but subsided after manual compression. The patients evaluated had significant differences in age and sex between the 2 groups (P values = .204 and .373, respectively).

The mean size of the 26 thyroid nodules on conventional US-CNB was 18.3 mm (range, 4–39 mm). The mean size of the 61 thyroid nodules by using the modified CNB technique was 22.3 mm (range, 7–60 mm) (P = .134). None of the patients evaluated had significant complications. In the modified technique, perinodular hemorrhage occurred in 1 patient immediately after US-CNB but subsided after manual compression.

All specimens obtained by using the 2 US-CNB methods demonstrated adequacy for diagnosis. The CNB results according to the Bethesda system recommended for practical use showed class II in 15 (57.7%) cases, class III in 9 (34.6%) cases, class IV in 1 (3.8%) case, and class VI in 1 (3.8%) case for the 26 nodules biopsied in the conventional group and class II in 7 (11.4%) cases, class III in 7 (11.4%) cases, class IV in 35 (57.4%) cases, class V in 1 (1.6%) case, and class VI in 11 (18.0%) cases for the 61 nodules biopsied in the modified method group, respectively. The rate of inconclusive US-CNB results was 34.6% (9/26) by using the conventional method and 11.4% (7/61) by using the modified technique (P = .018).

Surgical pathology on excision was present in 9 of 26 nodules in the conventional group and in 52 of 61 nodules in the modified technique group (Tables 2 and 3). The malignancy rate by surgical pathology was 33.3% (3/9) in the conventional group and 51.9% (27/52) in the modified group (P = .473), but this difference was not statistically significant. In the conventional group, surgical pathologies included nodular hyperplasia in 5 cases, chronic lymphocytic thyroiditis in 1 case, classic PTC in 2 cases, and medullary thyroid carcinoma in 1 case (Fig 2). In the modified technique group, final pathology in 52 patients included nodular hyperplasia in 5 cases, follicular adenoma in 19 cases, nodular Hashimoto thyroiditis in 1 case, follicular variant of PTC in 13 cases, classic PTC in 8 cases, follicular carcinoma in 5 cases, and Warthin-like variant of PTC in 1 case (Fig 3).

Results

The clinical parameters and final CNB results are summarized in Table 1. Of the 26 patients in the conventional group (age range, 34–62 years; mean age, 46.6 years), 3 (11.5%) were men and 23 (88.5%) were women. Of the 60 patients in the modified technique group (age range, 26–73 years; mean age, 49.7 years), 12 (20%) were men and 48 (80%) were women. There were no significant differences in age and sex between the 2 groups (P values = .204 and .373, respectively).

The mean size of the 26 thyroid nodules on conventional US-CNB was 18.3 mm (range, 4–39 mm). The mean size of the 61 thyroid nodules by using the modified CNB technique was 22.3 mm (range, 7–60 mm) (P = .134). None of the patients evaluated had significant complications. In the modified technique, perinodular hemorrhage occurred in 1 patient immediately after US-CNB but subsided after manual compression.

All specimens obtained by using the 2 US-CNB methods demonstrated adequacy for diagnosis. The CNB results according to the Bethesda system recommended for practical use showed class II in 15 (57.7%) cases, class III in 9 (34.6%) cases, class IV in 1 (3.8%) case, and class VI in 1 (3.8%) case for the 26 nodules biopsied in the conventional group and class II in 7 (11.4%) cases, class III in 7 (11.4%) cases, class IV in 35 (57.4%) cases, class V in 1 (1.6%) case, and class VI in 11 (18.0%) cases for the 61 nodules biopsied in the modified method group, respectively. The rate of inconclusive US-CNB results was 34.6% (9/26) by using the conventional method and 11.4% (7/61) by using the modified technique (P = .018).

Surgical pathology on excision was present in 9 of 26 nodules in the conventional group and in 52 of 61 nodules in the modified technique group (Tables 2 and 3). The malignancy rate by surgical pathology was 33.3% (3/9) in the conventional group and 51.9% (27/52) in the modified technique group (P = .473), but this difference was not statistically significant. In the conventional group, surgical pathologies included nodular hyperplasia in 5 cases, chronic lymphocytic thyroiditis in 1 case, classic PTC in 2 cases, and medullary thyroid carcinoma in 1 case (Fig 2). In the modified technique group, final pathology in 52 patients included nodular hyperplasia in 5 cases, follicular adenoma in 19 cases, nodular Hashimoto thyroiditis in 1 case, follicular variant of PTC in 13 cases, classic PTC in 8 cases, follicular carcinoma in 5 cases, and Warthin-like variant of PTC in 1 case (Fig 3).

Of the circumscribed solid nodules without malignant US

### Data and Statistical Analysis

The conclusiveness of CNB results, age, tumor size, and malignancy rate were compared between the conventional and modified technique groups by using Student t and Fisher exact tests, respectively. Data were analyzed by using SAS software, Version 9.4 (SAS Institute, Cary, North Carolina). All P values were 2-sided, and P < .05 was considered statistically significant.
features, the most common malignancy was a follicular variant of PTC in 13 (43.3%) of 30 malignancy cases, and the most frequent benign pathology was follicular adenoma in 19 (61.3%) of 31 benign lesions.

DISCUSSION

Our study demonstrated that the rate of inconclusive US-CNB results in the modified technique group was significantly lower than that in the conventional group for circumscribed solid nodules without malignant US features (11.4% versus 34.6%, \( P = .004 \)). The main issue of the present study was circumscribed solid nodules with indeterminate cytology, which addressed follicular neoplasm rather than PTC because of the presence of nodules without evidence of malignant US features indicating PTC. This modified biopsy technique is essential to differentiate follicular neoplasm from adenomatous nodules because visualization of the capsule in the specimen helps pathologists change their findings from follicular lesions of undetermined significance to follicular neoplasm, while the absence of the capsule implies nodular hyperplasia. This technique can improve identification of surgical candidates. As shown by our results, the percentage of the benign diagnoses decreased in the second cohort by using the modified technique, whereas the percentage of follicular neoplasms increased, as did the percentage of malignancies.

Although a previous study has already described this technique, it did not evaluate its effectiveness compared with a conventional method and concentrate on problematic nodules separately at diagnosis by using routinely performed conventional CNB methods. These problematic nodules should be diagnosed on US before any intervention. Circumscribed solid nodules without malignant features are considered an indeterminate category on US. These nodules are a challenge for risk stratification using US, FNA, and even conventional CNB due to the impossibility of capsule assessment. Previous reports have shown that the CNB method is more useful than repeat FNA for the evaluation of nodules that are inconclusive on FNA. These studies reported that the rate of inconclusive CNB results ranged between 0% and 26%. Recently, Hahn et al demonstrated that US-CNB is beneficial for the diagnosis of thyroid nodules with inconclusive US-guided FNA results. However, it is still not helpful for the differential diagnosis in 36% of nodules that are suspicious for follicular neoplasm on US, as shown by the occurrence of several indeterminate results in the differentiation of nodular hyperplasia from follicular neoplasm even after US-CNB. Nodular hyperplasia is one of the most common benign lesions of the thyroid and does not require further treatment in most patients. However, follicular neoplasms should be surgically treated because the differentiation of a follicular adenoma from a follicular carcinoma is impossible without the evaluation of the whole capsule. Unfortunately, this modified CNB technique is inadequate to differentiate benign and malignant follicular neoplasms. However, reliable diagnosis of nodules with any evidence of follicular neoplasm via presurgical interventions prevents unnecessary surgery in those patients with simple nodular hyperplasia and gives reassurance to anxious patients who are not candidates for surgery.

In the cases in which surgical pathology was available, the most common malignant subtype in circumscribed solid thyroid nodules without malignant US features with indeterminate cytology was a follicular variant of PTC, with 13 (43.3%) cases of 30 malignancies. The follicular variant of PTC frequently has cytologi-
cally inconclusive results without definite malignant features on US. This result supports a previous report in which the follicular variant of PTC showed more benign US features, and the diagnostic rate of PTC on FNA was lower compared with classic PTC. Further studies about whether CNB is better than FNA for the preoperative diagnosis of the follicular variant of PTC are needed.

Previous reports have suggested that the incidence of conventional CNB-related hematoma was approximately 0%–1.5%. In the modified capsular biopsy technique group, 1 patient had subsequent perinodular hemorrhage, which was resolved by manual compression. Perinodular hemorrhages infrequently occur even in FNA by using 23- to 25-gauge needles. Color Doppler US has to be routinely used to avoid hypervascularized perinodular vessels when the tract for biopsy is determined.

Our study has some limitations. First, this retrospective study compared the results of procedures performed in 2 different periods. Therefore, although some unidentified confounding factors may be present, we could not retrospectively estimate them, and prospective studies would be more adequate in this context. Second, the sample size was small. We did not actively perform US-CNB in the former study period because the management of inconclusive cytologic nodules was routinely performed by using repeat FNA or surgery in our institution. Third, selection bias due to technical problems associated with the biopsies may exist. In case of thyroid nodules large enough to occupy the entire ipsilateral thyroid gland, biopsying the thyroid capsule is not easy because the needle can potentially damage extrathyroidal structures. The modified technique may present limitations in biopsying large nodules and preserving normal parenchyma. The most problematic factor of CNB in small nodules (< 1 cm) would be target size. If small lesions are well-targeted, the results should be reliable because the notch can be properly positioned within the specimen to encompass 7 mm of throw.

CONCLUSIONS

For circumscribed solid thyroid nodules without malignant sonographic features and with indeterminate cytopathology, the US-CNB technique containing the nodule, capsular portion, and surrounding parenchyma enhances diagnostic yield compared with a conventional CNB method that biopsied only the internal portion of the nodule. This technique reduces the frequency of inconclusive CNB results and properly selects surgical candidates.
