Flow Conditions in the Intracranial Aneurysm Lumen Are Associated with Inflammation and Degenerative Changes of the Aneurysm Wall

ABSTRACT

BACKGROUND AND PURPOSE: Saccular intracranial aneurysm is a common disease that may cause devastating intracranial hemorrhage. Hemodynamics, wall remodeling, and wall inflammation have been associated with saccular intracranial aneurysm rupture. We investigated how saccular intracranial aneurysm hemodynamics is associated with wall remodeling and inflammation of the saccular intracranial aneurysm wall.

MATERIALS AND METHODS: Tissue samples resected during a saccular intracranial aneurysm operation (11 unruptured, 9 ruptured) were studied with histology and immunohistochemistry. Patient-specific computational models of hemodynamics were created from preoperative CT angiographies.

RESULTS: More stable and less complex flows were associated with thick, hyperplastic saccular intracranial aneurysm walls, while slower flows with more diffuse inflow were associated with degenerated and decellularized saccular intracranial aneurysm walls. Wall degeneration \( (P = .041) \) and rupture were associated with increased inflammation \( (CD45^+/H1 \leq 0.05) \). High wall shear stress \( (P = .018) \), higher vorticity \( (P = .046) \), higher viscous dissipation \( (P = .046) \), and high shear rate \( (P = .046) \) were associated with increased inflammation. Inflammation was also associated with lack of an intact endothelium \( (P = .034) \) and the presence of organized luminal thrombosis \( (P = .018) \), though overall organized thrombosis was associated with low minimum wall shear stress \( (P = .034) \) and not with the flow conditions associated with inflammation.

CONCLUSIONS: Flow conditions in the saccular intracranial aneurysm are associated with wall remodeling. Inflammation, which is associated with degenerative wall remodeling and rupture, is related to high flow activity, including elevated wall shear stress. Endothelial injury may be a mechanism by which flow induces inflammation in the saccular intracranial aneurysm wall. Hemodynamic simulations might prove useful in identifying saccular intracranial aneurysms at risk of developing inflammation, a potential biomarker for rupture.

ABBREVIATIONS: max = maximum; OSI = oscillatory shear index; sIA = saccular intracranial aneurysm; VO = vorticity; WSS = wall shear stress

Saccular intracranial aneurysm (sIA) is a relatively common disease (estimated prevalence, 2%–3%). This is often undisagnosed because of a lack of symptoms but may cause a devastating intracranial hemorrhage. Some patients die immediately after sIA rupture, and of those patients who make it to the hospital after sIA rupture, 27% die despite neurosurgical intensive care. Because of the sinister outcome of sIA rupture, many diagnosed unruptured sIAs are treated to prevent rupture. However, many, if not most, sIAs do not rupture during life-long follow-up. Moreover, currently, sIA rupture can be prevented only by invasive procedures (endovascular or microsurgical occlusion) with a significant risk of morbidity and even mortality. It is therefore extremely important to distinguish rupture-prone sIAs from those that will never rupture, especially because unruptured sIAs are being diagnosed with increasing frequency due to improved access to MR imaging and other imaging studies of the brain.

An aneurysm wall ruptures when the wall strength is exceeded by the mechanical stress imposed on it. Wall strength depends on wall structure, which is dependent on the cellular and extracellular composition of the sIA wall. The characteristics of the cellular and extracellular composition of the ruptured or rupture-prone sIA wall, mainly damage to the endothelium, inflammation, and loss of mural cells, have been previously reported by us and others.\(^5\) The cause of these histologic changes, which we refer to as “degenerative remodeling” remains unknown.

We have previously described the potential mechanism by which nonphysiologic flow conditions can trigger degenerative remodeling of the sIA wall via damage to the endothelium.\(^10,11\) In addition, we and others have previously shown that flow and wall shear stress (WSS) differ in ruptured and unruptured sIAs\(^12\) and that these flows are associated with changes in sIA morphology.\(^15\) The association of flow and WSS with sIA rupture suggests that they affect sIA wall structure, the main determinant of rupture risk.

Here we studied the possible association of hemodynamics with the histologic changes of the sIA wall. We focused especially on wall degeneration, inflammatory cell infiltration, and damage to the endothelium.

### MATERIALS AND METHODS

#### Patients and Tissue Samples of Intracranial Aneurysms

Patients with intracranial aneurysms that underwent surgical clipping were considered for the study. Twenty patients with preoperative 3D imaging necessary for computational fluid dynamics analysis were included (On-line Table 1). During the surgical intervention, after placement of the clip, a tissue sample was harvested from the aneurysm dome for histology and immunohistochemical analysis. The size of the tissue sample excised from the aneurysm wall varied depending on the size of the aneurysm and how the aneurysm was clipped (Fig 1). Of these 20 patients, 10 were included in a prior histopathologic study by our group.\(^17\)

The study was approved by the ethics committee of Helsinki University Central Hospital, and patients gave informed consent to participate in the study.

#### Histology and Immunohistochemistry

The 20 aneurysm tissue samples underwent immunostaining against CD45 (pan-leukocyte marker, clone 2B11 + PD7/26, dilution 1:400; DAKO, Glostrup, Denmark; Fig 1). The degree of inflammation in the sIA wall was quantified by calculating the number of CD45-positive cells per standardized surface area (0.613 mm\(^2\)) under a \(\times20\) magnification from 1 to 3 hotspots in the intracranial aneurysm wall. Degenerative remodeling of the sIA wall was scored from hematoxylin-eosin staining by using a previously described scale based on the cellular composition of the sIA wall and the structure of the sIA wall extracellular matrix.\(^6\) This scale is associated with the rupture rate.\(^6\) The presence of fresh or organized luminal thrombus was assessed from hematoxylin-eosin staining. The presence of endothelium on the luminal surface was scored from CD31 immunostainings according to the morphology of the cell and positivity to CD31 (Fig 1, CD31 data available for only a subset of 10 aneurysms) as described previously by Ollikainen et al.\(^17\)

#### Computational Flow Analysis

Image-based computational fluid dynamics models were constructed from preoperative 3D CT angiography images.\(^18\) CTA images consisted of approximately 250 axial sections with 512 \(\times\) 512 pixels and a typical voxel resolution of 0.4 \(\times\) 0.4 \(\times\) 0.6 mm. Pulsatile flow simulations were performed by solving the 3D incompressible Navier-Stokes equations by using finite elements on unstructured grids.\(^19\) The computational meshes had a resolution of 200 \(\mu\)m and contained between 2 and 5 million elements. Inflow boundary conditions were prescribed by using the Womersley velocity profile\(^20\) and flow waveforms derived from flow measurements in healthy subjects.\(^21,22\) Inflow rates were scaled with the inlet area according to the Murray law,\(^23\) and mean flows ranged from approximately 1.2 to 4.1 mL/s. Outflow conditions were prescribed by splitting the outflow rates according to the principle of minimum work (Murray law).\(^23\) Vessel walls were assumed rigid, and blood was approximated as a Newtonian fluid with a density of \(\rho = 1.0\) g/cm\(^3\) and a viscosity of 0.04-\(\mu\)m poise. Numeric solutions were obtained for 2 cardiac cycles by using 100
time-steps per cycle. Flow fields corresponding to the second cycle were saved for analysis.

To characterize the aneurysm hemodynamic environment, we computed a number of flow variables over the aneurysm region (On-line Table 2). Exact mathematic definitions of these quantities are given by Mut et al.24 Our choice of mesh resolution and time-step size has been shown to be adequate for accurate quantification of the spatial and time-averaged quantities considered in this work.25

**Geometric Analysis**

The geometry of the aneurysm (ie, its size and shape) was characterized by automatically computing several geometric variables by using 3D vascular reconstruction (On-line Table 3). Definitions of these quantities and a physical explanation of their meaning can be found in Ma et al26 and Raghavan et al.27

**Statistical Analysis**

Because our hypothesis was that it is the nonphysiologic WSS (whether too high or too low) but not the physiologic WSS that triggers the degenerative remodeling and inflammation of the sIA wall,10 we classified our aneurysms accordingly into groups of low, mid-, or high WSS instead of directly comparing WSS with wall remodeling or inflammation. Because there is no clear definition for what constitutes the physiologic range of WSS, especially in a saccular intracranial aneurysm, we classified our aneurysms according to the median of the time and sac-averaged WSS.

In this series, flow-related hemodynamic variables did not significantly differ between ruptured and unruptured sIAs (On-line Table 3). Of the studied geometric variables, only the ellipticity index (P = .047) and Gaussian curvature (P = .047) were associated with rupture (On-line Table 4).

Compared with sIAs with walls that have a histology most resembling the composition of the normal arterial wall (A type, n = 2), sIAs with both thick walls and hyperplasia of mural cells (B-type walls, n = 10) as well as degenerated walls with loss of mural cells (C type, n = 8) had less oscillatory flows (lower oscillatory shear index [OSI] and maximum oscillatory shear index [OSImax], Table 1). Interestingly, thick hyperplastic walls were also associated with simpler and more stable flows (lower corelen, vortex core line length, a measure of flow complexity; and lower podent, proper orthogonal decomposition entropy, a measure of flow instability; Table 1), whereas loss of mural cells was associated with slower and more diffuse inflows (Table 1).

Degenerated walls characterized by loss of mural cells were associated with increased infiltration of inflammatory cells (wall types B versus C, P = .011; A versus C, P = .041). In addition to wall degeneration, inflammation was associated with rupture (P = .031, Fig 2A).

**RESULTS**

**Factors Associated with Wall Degeneration and Rupture: Inflammation**

In this series, flow-related hemodynamic variables did not significantly differ between ruptured and unruptured sIAs (On-line Table 3). Of the studied geometric variables, only the ellipticity index (P = .047) and Gaussian curvature (P = .047) were associated with rupture (On-line Table 4).

Compared with sIAs with walls that have a histology most resembling the composition of the normal arterial wall (A type, n = 2), sIAs with both thick walls and hyperplasia of mural cells (B-type walls, n = 10) as well as degenerated walls with loss of mural cells (C type, n = 8) had less oscillatory flows (lower oscillatory shear index [OSI] and maximum oscillatory shear index [OSImax], Table 1). Interestingly, thick hyperplastic walls were also associated with simpler and more stable flows (lower corelen, vortex core line length, a measure of flow complexity; and lower podent, proper orthogonal decomposition entropy, a measure of flow instability; Table 1), whereas loss of mural cells was associated with slower and more diffuse inflows (Table 1).

**Factors Associated with Aneurysm Wall Inflammation: High Flow Conditions and Endothelial Damage**

Inflammation was associated with WSS (Figs 2B and 3). The degrees of wall inflammation (CD45+ cells) in each WSS group are presented in Fig 2B. Aneurysms with high WSS (n = 4) had larger numbers of inflammatory cells than sIAs with mid-WSS levels (n = 9, P = .188). Also sIAs with low WSS (n = 7) had somewhat higher numbers of inflammatory cells than sIAs with mid-WSS levels, though the difference did not reach statistical significance. Other flow characteristics associated with increased inflammation were higher vorticity (VO, P = .046), higher viscous dissipation (P = .046), and higher shear rate (P = .046). Heterogeneity in the distribution of WSS across a single aneurysm sac was associ-
ated with heterogeneity in the number of CD45+ cells across the wall (P = .035), suggesting that interactions leading to the association of high WSS and inflammation might happen focally at the wall. More inflammatory cells (CD45+) were found in sIA walls that lacked an intact endothelium (P = .034, Table 2), as well as in sAs with organized thrombus (P = .018), suggesting that damage to the endothelium may mediate the association of flow and inflammation.

Factors Associated with Endothelial Damage: High Flow Conditions
Lack of an intact endothelium was associated with higher vorticity (P = .034), higher viscous dissipation (P = .020), and higher shear rate (P = .034), similar to inflammation. In addition, lack of an endothelium was associated with lower OSI (P = .034), similar to wall remodeling (B- and C-type walls compared with A-type walls). In this series, the sAs that lacked an intact endo-

Note: ICI indicates inflow concentration index; Q, inflow rate into the aneurysm; corelen, vortex core line length; OSI, maximum OSI value; OSI, proper orthogonal decomposition entropy, a measure of flow instability. Median and range are given for the hemodynamic variables in each wall type group, and corresponding P values for comparisons between groups are given. pAB = P value (A vs B), pAC = P value (A vs C), pBC = P value (B vs C). Group A is defined by an intact-looking wall with linearly organized smooth muscle cells and intact endothelium; group B, by smooth muscle cell hyperplasia; and group C, by loss of smooth muscle cells and endothelial cells complemented by degeneration of the extracellular matrix and luminal thrombosis.

gested possible mechanisms by which pathologic flow conditions have been previously shown to be associated with sIA rupture.31 Moreover, even if not the cause of wall degeneration, inflammation modulates the remodeling of the sIA wall.40

thelium were smaller ($P = .020$), had smaller necks ($P = .020$), and had increased undulation ($P = .034$) and ellipticity ($P = .011$, Table 2).

DISCUSSION
Degenerative wall remodeling, inflammation, and nonphysiologic flow conditions have been previously shown to be associated with sIA rupture.6,13,14,28 Although we and others have suggested possible mechanisms by which pathologic flow conditions may lead to degenerative wall remodeling,10,12,16,29 this is the first study that compares in vivo flow conditions with the histology of human intracranial aneurysms.

Flow Conditions Associated with Degenerative Wall Remodeling and Inflammation
We have previously shown that loss of mural smooth muscle cells leads to aneurysm growth and rupture in experimental models9 and is associated with rupture in human sIAs.30 The cause of smooth muscle cell loss and the degenerative remodeling in human aneurysms is still unknown, but inflammation of the sIA wall has been suggested as a potential cause of the degenerative remodeling that predisposes to rupture.31 Moreover, even if not the cause of wall degeneration, inflammation modulates the remodeling of the sIA wall.7,10

In this series, proliferative (hyperplasia) wall remodeling was associated with simple, stable flows, whereas degenerative remodeling (loss of cells and damage to the extracellular matrix) was associated with slower and diffuse inflows. Whether simple, stable flows are needed for the proliferative remodeling, whereas slower and diffuse inflows trigger degenerative processes leading to cell death in the sIA wall remains to be determined. Inflammation of the sIA wall was significantly associated with high flow conditions (Figs 3 and 4), but not with flow conditions that were associated with degenerative remodeling and loss of mural cells (C-type walls). This finding could suggest that flow patterns and hemodynamic stress may affect sIA wall remodeling, including mural smooth muscle cell proliferation and cell death, independent of wall inflammation. Moreover, it suggests that part of the inflammatory cell response in the sIA wall may be induced by high flow conditions, independent of the wall remodeling.

Flow-Mediated Endothelial Damage as the Trigger of Wall Remodeling and Inflammation?
Endothelial cells are sensors of WSS in the arterial wall.32 They contribute to the control of blood flow in the vessel by regulating muscle tone in the vessel wall and subsequently vessel diameter.32 Endothelial cells also maintain a very important barrier function between the bloodstream and the vessel wall32–34 and actively prevent luminal thrombosis.35

The proper function of endothelial cells is very easily disturbed by nonphysiologic (either too high or too low) WSS.32–34

In our series, sIAs that lacked an intact endothelium had more inflammation, and lack of an endothelium was associated with flow conditions similar to those of inflammation. These similar associations among flow conditions, wall inflammation, and loss of endothelial cells suggest that endothelial damage caused by nonphysiologic flow conditions can be a mechanism by which flow conditions trigger or modulate inflammation in the sIA wall.

Although this is the first study to demonstrate associations with sIA wall degeneration and flow conditions in vivo in true sIAs in patients, aberrant flow conditions have been suspected as promoters of sIA wall degeneration, growth, and rupture before.10,16,31 Loss of an intact endothelium is characteristic of ruptured sIAs and of degenerated sIA walls.5,6 Loss of endothelium exposes thrombogenic matrix surfaces35 and thus predisposes to thrombus formation, which is also characteristic of ruptured sIAs and of degenerated sIA walls.5,6 Thrombus can trigger and promote wall degeneration via several mechanisms that cause cell death and proteolytic injury.10,16,38 In this series, high inflammation (CD45+) was found in sIAs with organized thrombus (older thrombus) but not in sIAs with only fresh thrombus, suggesting that the prolonged presence of thrombus or degradation of the thrombus with time is what increases inflammation in the sIA wall.

Clinical Implications
Both high and low WSS have previously been implicated as promoters of sIA wall degeneration.12–14,39 Most interesting, in this series, high WSS and conditions of high flow in general (high shear rate, high vorticity, high viscous dissipation) were associated with inflammation, whereas low flow was associated with a degenerated wall that had lost mural cells. The observation that different types of flow were associated with distinct histologic changes suggests that flow may affect sIA wall remodeling via several mechanisms and that flow conditions can induce different changes in the sIA wall at different time points during the remodeling of the sIA wall.40

b Significant.
Although it is still unclear whether inflammation is the cause of sIA rupture or a reaction to the cause of the degenerative remodeling that predisposes to rupture, inflammation is clearly an indicator of a degenerated, rupture-prone sIA wall, as demonstrated by histopathologic studies and by ferumoxytol-based MR imaging of inflammatory cells in the sIA wall in patients.

We now demonstrate that flow conditions determined with patient-specific computational fluid dynamics simulations are associated with the presence of inflammation in the sIA wall. This finding supports the concept that patient-specific flow simulations could be used to distinguish those sIAs that will develop wall inflammation and thus would require either more frequent follow-up imaging or perhaps even more active treatment. Most important, our results also show that computerized geometric indexes are not similarly associated with wall inflammation and cannot replace flow simulations, even if sIA and parent artery geometry are some of the main determinants of flow conditions in the aneurysm.

In this series, flow dynamics was associated with wall inflammation and with other histologic changes in the sIA wall in small sIAs. Because it is well-established that risk of sIA rupture increases with sIA size, but that many of the sIAs that do rupture are small, it is particularly useful to develop novel diagnostic tools that would predict rupture risk in small sIAs that otherwise would be mistaken for benign, low risk lesions.

Limitations of the Study and Topics for Further Studies

Our series is a highly selected one, with bias in sIA size and clinical risk factors. This kind of selection bias is unavoidable in any kind of study that uses patient-derived tissue samples collected intraoperatively. Moreover, because not all sIAs undergo an operation and not all of those that do are suitable for the acquisition of tissue samples, our series is somewhat limited in number of samples and statistical power. Computational fluid dynamics models make several assumptions and are constructed from CTA images with limited resolution, which could affect the representation of the intrasaccular flows, especially for aneurysms with narrow necks. Our findings need to be replicated in other, similar or larger patient series and in experimental models. Experimental models and computer simulations with cell-cell interaction are needed to establish causality between the different associations and to provide mechanistic insight.

Most interesting, in this series that focused on the time- and space-averaged flow conditions in the whole sIA, heterogeneity in the distribution of WSS across the aneurysm sac was associated with heterogeneity in the number of CD45+ cells in the wall. This finding suggests that the flow-induced cellular interactions that lead to increased inflammation (eg, loss of endothelial cells) might happen focally at the wall. Further studies should include histologic data from different regions of the sIA wall and spatial registration of these histologic changes with focal flow conditions. These studies are also needed to confirm our findings because sIA walls are highly heterogeneous in structure (Fig 1) and this local variation in the aneurysm wall may have biased our results because we were not able to analyze the histology of the whole sIA wall.

In addition, flow simulations need to be correlated with the biology of the sIA wall and the structural strength of the aneurysm wall, to develop a diagnostic tool from computational fluid dynamics models. This requirement is paramount to understand how different kinds of flow patterns affect the sIA wall, which is critical to properly use this technology in diagnostics.

CONCLUSIONS

We show that flow conditions in saccular intracranial aneurysms are associated with inflammation and other histologic changes in the aneurysm wall. In particular, high- and low-flow conditions are associated with different wall changes. This study suggests that computational simulations that determine patient-specific flow conditions could be used to identify aneurysms at risk for devel-
opining inflammation and other rupture-associated changes in their walls.

Degenerative wall remodeling, inflammation, and nonphysiologic flow conditions have been previously shown to be associated with sIA rupture.6,13,14,28 Although we and others have suggested possible mechanisms by which pathologic flow conditions may lead to degenerative wall remodeling,10,12,16,29 this is the first study that compares in vivo flow conditions with the histology of human intracranial aneurysms.
