The Diagnostic Accuracy of Contrast-Enhanced CT of the Neck for the Investigation of Sialolithiasis

Y.M. Purcell, R.G. Kavanagh, A.M. Cahalane, A.G. Carroll, S.G. Khoo, and R.P. Killeen

ABSTRACT

BACKGROUND AND PURPOSE: Sialolithiasis is a common benign pathology affecting the salivary glands but it is unclear if contrast-enhanced CT, which is commonly used for investigation of head and neck pathology, can identify calculi as accurately as noncontrast CT. The aim of this study was to assess the diagnostic accuracy of contrast-enhanced CT of the neck in the diagnosis of sialolithiasis compared with noncontrast CT of the neck used as the criterion standard.

MATERIALS AND METHODS: This was a retrospective, case-control study of 92 consecutive cases in 90 patients who underwent both noncontrast CT of the neck and contrast-enhanced CT of the neck in 2 tertiary referral centers from January 2011 to December 2015 for investigation of sialolithiasis. Axial 3-mm-section images were assessed by a fellowship-trained diagnostic neuroradiologist and diagnostic neuroradiology fellow in consensus. Blinded assessment of the contrast-enhanced CT of the neck was performed first, followed by noncontrast CT of the neck after a 2-week interval. The presence or absence of a stone and stone location and size were documented. Statistical analysis was undertaken to assess the agreement between CT protocols and calculate the sensitivity and specificity of contrast-enhanced CT of the neck.

RESULTS: Fifty calculi were identified on noncontrast CT of the neck in 31 cases; and 48 calculi, in 31 cases on contrast-enhanced CT of the neck. No calculi were identified in the remaining 61 cases. The sensitivity and specificity of contrast-enhanced CT of the neck in the detection of sialolithiasis was 96% (95% CI, 86.3%–99.5%) and 100% (95% CI, 94.1%–100%), respectively. The positive predictive value of contrast-enhanced CT of the neck was 100% (95% CI, 92.6%–100%), and the negative predictive value was 96.8% (95% CI, 89%–99.6%). The accuracy of contrast-enhanced CT of the neck in diagnosing the presence or absence of salivary calculus was 98%.

CONCLUSIONS: Contrast-enhanced CT of the neck is accurate in the detection of sialolithiasis, with no difference in diagnostic accuracy compared with noncontrast CT of the neck.

ABBREVIATIONS: CECTN = contrast-enhanced CT of the neck; NCCTN = noncontrast CT of the neck

Sialolithiasis is defined as the formation of calculi within the salivary glands. It is the most common non-neoplastic condition that affects them. Calculi, which are often multiple, cause partial or complete obstruction of the salivary duct, resulting in obstructive sialadenitis, which may manifest as acute or chronic unilateral gland swelling and pain. Symptoms typically arise during eating because chewing food precipitates salivation. Sialadenitis can be complicated by bacterial infection and abscess formation. While calculi in the distal submandibular duct may be readily detectable clinically by bimanual palpation, calculi in the proximal submandibular duct or gland and parotid duct or gland depend on imaging for diagnosis.

Noncontrast CT of the neck (NCCTN) has been recommended for the evaluation of salivary calculi because it is sensitive for the detection of calcifications. One of the drawbacks of NCCTN is that it provides less detail of duct dilation and intraductal or glandular pathology than contrast-enhanced CT of the neck (CECTN). Traditionally, the use of CECTN in this setting has been in addition to the NCCTN rather than as a stand-alone test. Concerns have been raised that on CECTN, blood vessels may simulate small sialoliths and lead to a false-positive diagnosis or reduce diagnostic certainty. CECTN has been used for the evaluation of complicated stone disease in a suspected abscess or an inflammatory process after calculi have been identified on imaging.
NCCTN.9,11,12 The use of NCCTN alone gives less detail of glandular and periglandular inflammation.9 The addition of CECTN, however, will cause an increase in the patient radiation dose.

The purpose of this study was to determine the accuracy of CECTN alone in the detection of salivary calculi compared with NCCTN alone. A secondary objective was to calculate the patient radiation dose when performing both NCCTN and CECTN.

MATERIALS AND METHODS

Subjects

This retrospective, case-control study was conducted at St. Vincent’s University Hospital, a tertiary care, university-affiliated medical center in Dublin, Ireland. The local institutional review board approved this study and waived the requirement for written informed consent.

An electronic search was performed of all consecutive CT neck examinations performed during a 5-year period between January 1, 2011, and December 31, 2015, using the search terms “calculus/calculi,” “stone/stones,” and “sialolith.” Data were collected by electronic query of the hospital Radiology Information System section. In addition, we recorded the following data: patient demographics (age and sex), the referral source, and the presence of calculi.

The inclusion criteria were patients older than 16 years of age who had both a NCCTN and CECTN performed during a single visit for the investigation of suspected salivary stones.

CT Image Acquisition

NCCTN and CECTN were acquired on a 64-row multidetector CT scanner (Somatom Sensation 64; Siemens, Erlangen, Germany) in the craniocaudal direction with a collimation of 0.6 mm, gantry rotation of 500 ms, and a pitch of 0.9. Automated dose-control software was used with 120-kV (peak) and reference milliamperes—second (maximum, 200). For the CECTN, 100 mL of nonionic, iodinated low-osmolar contrast medium (Niopam, iopamidol, 340 mg I/mL; Bracco Imaging, Milan, Italy) was injected through a 20-ga or larger cannula, typically sited in the antecubital lumen (center = 100, width = 700), and bone (center = 500, width = 1500) window settings to optimize detection of calculi. These 3 standard window settings were adjusted manually for every case as the reviewers saw fit. The reviewers recorded the presence or absence of stones, stone location (submandibular or parotid system, gland, or duct; anterior or posterior portion of the duct), stone size, and number of stones. The size of each stone was expressed as the maximal diameter determined on a single axial section. In addition, we recorded the following data: patient demographics (age and sex), the referral source, and the presence of salivary gland masses in the study population.

Statistical Analysis

The accuracy of CECTN in determining the frequency and location of salivary calculi was compared with that of NCCTN used as the criterion standard. Descriptive values were used for patient and stone demographics (actual values, percentages). Statistical analysis was performed by using STATA Statistical Software, Release 12 (StataCorp, College Station, Texas). The sensitivity, specificity, and likelihood ratios were calculated for CECTN in the detection of salivary calculi, with the 95% confidence interval calculated as the measure of variance. The difference in the prevalence of sialolithiasis among different referrers was calculated with the χ2 test of proportions.

RESULTS

Our search yielded 370 potential cases performed during the 5-year study period. Of these, 92 sets of CT examinations in 90 patients met the inclusion criteria: age older than 16 years and both NCCTN and CECTN performed contemporaneously for the investigation of suspected salivary stones (1 patient had 3 sets of CT examinations) (Table). There were 38 male (42%) and 52 female (58%) patients with a mean age of 50 years (range, 20–85 years). Fifty calculi were identified in 31 patients on NCCTN (the criterion standard), which gives a prevalence of 34%. One patient had 8 calculi, 1 patient had 4 calculi, 1 patient had 3 calculi, 7 patients had 2 calculi, and 21 patients had 1 calculus. Calculi were not present in 59/90 patients (61/92 total cases) on NCCTN.

On CECTN, all patients were correctly categorized as having or not having salivary stones; 48 calculi were identified in 31 patients on CECTN compared with NCCT as the criterion standard.
Zero calculi were identified in the remaining 59 patients on CECTN (59/90 patients, 61/92 total cases).

The overall sensitivity of CECTN for the detection of salivary stones was 96% (95% CI, 86.3%–99.5%), and the specificity was 100% (95% CI, 94.1%–100%). The positive predictive value of CECT was 100% (95% CI, 92.6%–100%), and the negative predictive value was 96.8% (95% CI, 89%–99.6%). The positive likelihood ratio was infinity, and the negative likelihood ratio was 0.04 (95% CI, 0.01–0.16). The accuracy of CECTN in diagnosing the presence or absence of salivary stones in our study was 98%.

Two calculi were not identified on CECTN that were identified on the criterion standard NCCTN. Both missed calculi were asymptomatic. The first missed stone was a 1-mm calculus in the left parotid gland in a patient with multiple bilateral calculi and calcified lymph nodes, which, in retrospect, was visible on the CECTN.

Of the 92 CT studies, 73 (79.3%) referrals came from head and neck surgery; 14 (15.2%), from the emergency department; and 5 (5.4%), from other medical specialties (oncology, cardiology, nephrology, gastroenterology). Of the 73 referrals from head and neck surgery, 26 had calculi, which is a prevalence of 35.6%. Four of the 14 emergency department referrals and 1 of the 5 referrals from other sources had calculi, giving a prevalence of 28.6% and 20%, respectively. The difference in the prevalence of sialolithiasis among different referrers was not statistically significant using the χ² test of proportions (P = .44) (Table).

The exact locations of the 50 calculi identified are outlined in the Table. Seventy percent of the total calculi (35/50) were in the submandibular system; 38% (19/50), in the submandibular gland and 32% (16/50), in the submandibular duct. Thirty percent (15/50) of the total calculi were in the parotid system; 24% (12/50), in the parotid gland and 6% (3/50), in the parotid duct. The calculi ranged from 1 mm to 2 cm, with a mean diameter of 6 ± 5 mm.

We identified 3 masses: Fine-needle aspiration was performed in 2 cases, and the third case was lost to follow-up. Cytology demonstrated a benign cyst containing inflammatory debris, and the other case was suggestive of an acute inflammatory process with inflammatory cells and degenerate stromal elements.

The mean total dose-length product of the NCCTN was 290.8 mGy cm, and of the CECTN, it was 366.9 mGy cm. In patients having both CTS, the mean dose-length product was 692.7 ± 323.5 mGy cm. If the NCCTN had been omitted from each examination, the mean reduction in the effective dose would have been 1.6 mSv, with a standard neck conversion factor of 0.0059, assuming the use of a head CT dose phantom of 16 cm. This is a mean relative dose reduction of 42% per case.

**DISCUSSION**

Sialolithiasis is the most common benign disorder of the salivary glands. Eighty percent to 90% of calculi are found in the submandibular system, due to the more viscous, alkaline saliva and upward drainage of the duct promoting stasis. Parotid and sublingual calculi account for only 5%–10% and 0%–5% of cases, respectively. In our study, 70% of the total calculi (35/50) were
located in the submandibular system; 38% (19/50), in the submandibular gland and 32% (16/50), in the submandibular duct. This figure is slightly less than rates published in the literature and may be because we only imaged symptomatic patients; those with small calculi may be asymptomatic or those with distal ductal calculi may be clinically managed without imaging. Thirty percent (15/50) of the total calculi were in the parotid system; 24% (12/50), in the parotid gland and 6% (3/50), in the parotid duct. Postmortem studies have indicated that the prevalence of salivary calculi in the population is 1.2%.10,16,17 The peak incidence occurs from 30 to 60 years of age.5 The mean patient age in our study was 50 years, with a range of 25–85 years and a slight female preponderance of 57% (Table), correlating with that in previously published reports.18 Clinically symptomatic calculi are less frequent; an incidence of 27–59 cases per million population per year was reported in a review of 15 health regions in England between 1991 and 1995, though a higher incidence rate than previously reported was demonstrated in a nationwide population-based study by Schroder et al.18 of 14.10 per 100,000 person-years.4,19,20 The prevalence of salivary calculi in our study was 34%. There was no significant difference in stone prevalence between patient groups referred by different specialties using the $\chi^2$ test of proportions ($P = .44$).

Imaging techniques available for investigation of salivary calculi include conventional radiography, digital subtraction sialography, sonography, CT, and MR sialography. Conventional radiography is dependent on stone composition, and only about 20% of calculi are radiopaque.21 The sensitivity of digital subtraction sialography ranges from 96% to 100%, and the specificity, from 88% to 91%.22 It is contraindicated in the acute setting due to the potential exacerbation of symptoms associated with infection.9 Sonography has been reported to have a sensitivity ranging from 59.1% to 93.7%, and a specificity, from 86.7% to 100%.22,23 The sensitivity and specificity of MR imaging sialography have been reported to be 91% and 94%–97%, respectively.19

CT of the neck with and without contrast is given a rating of 5 by the American College of Radiology, defined as “may be appropriate,” in selected cases if a sialolith is suspected.11 The disadvantage of NCCTN is the lack of detail about potential complications of an obstructing calculus or an alternative diagnosis, such as a salivary tumor.12 CECTN, while useful for delineation of glandular inflammation or abscess, carries with it the risks associated with intravenous contrast such as allergy, anaphylaxis, extravasation, acute kidney injury, and so forth. Performance of both techniques results in an additional radiation dose to the patient. In our study, a mean reduction in effective dose of 1.6 mSv or a mean relative dose reduction of 42% per case would have been achieved if NCCTN had been omitted from the protocol (using a standard neck conversion factor of 0.0059, assuming use of a head CT dose phantom of 16 cm).

Contrary to previous reports that postulated that contrast may obscure visualization of a calculus,9,11 there were no false-positives in our study; calculi can be confidently diagnosed on CECTN. This is the first study, to our knowledge, to directly compare CECTN with

---

**FIG 2.** Potential false-positives. A and B, Calcified lymph nodes. C, Bilateral calcification of the stylohyoid ligaments (arrows). D, Calcification of the left stylohyoid ligament (arrow) with an adjacent tonsillolith (asterisk) in the left palatine tonsil.

**FIG 3.** Potential false-negative. A, Axial contrast-enhanced CT. Significant streak artifacts in the floor of the mouth due to dental amalgam. B, Single section inferiorly with windows adjusted manually, revealing an obstructing calculus (arrow) in the right anterior submandibular duct. One should be cautious when analyzing the floor of the mouth because this is a classic location for obstructing submandibular duct calculi and can easily be missed.
CONCLUSIONS

Contrast-enhanced CT of the neck is accurate in the diagnosis of salivary calculi. If single-phase CECTN instead of dual-phase CT (NCCTN and CECTN) is performed, there is a potential to reduce the effective radiation dose to the patient.
