Melanoma of the Sinonasal Tract: Value of a Septate Pattern on Precontrast T1-Weighted MR Imaging

ABSTRACT

BACKGROUND AND PURPOSE: Various tumors of the sinonasal tract can exhibit high signal intensity on T1WI. The purpose of this study was to determine the value of a septate pattern on precontrast T1WI for diagnosing sinonasal melanoma.

MATERIALS AND METHODS: Retrospectively, 3 observers independently reviewed MR images of 31 histologically proved sinonasal melanomas with special attention to the presence or absence of a septate pattern on precontrast T1WI, defined as alternating hyperintense and hypointense striations on precontrast T1WI. For comparison, we evaluated the prevalence of a septate pattern on precontrast T1WI in 106 nonmelanomatous sinonasal malignant tumors with 16 different histologic types. We also tried to identify the histopathologic features responsible for the septate pattern on precontrast TIWI.

RESULTS: Twenty-seven (87.1%) of 31 sinonasal melanomas showed hyperintense foci on T1WI, among which a septate pattern on precontrast T1WI was seen in 23 (74.2%), while 22 (20.8%) of 106 nonmelanomatous malignant tumors demonstrated hyperintense foci on T1WI, among which only 3 (2.8%) showed a septate pattern on precontrast T1WI. The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of a septate pattern on precontrast T1WI for the diagnosis of sinonasal melanoma were 74%, 97%, 88%, 93%, and 92%, respectively. Although limited due to the retrospective nature, 4 of 23 histologically reviewed sinonasal melanomas revealed an uneven distribution of melanin with alternating melanin and fibrous bands within the tumors.

CONCLUSIONS: A septate pattern on precontrast T1WI might be an adjunctive imaging finding for the diagnosis of sinonasal melanoma. This might be attributed histologically to an uneven distribution of melanin and hemorrhage within the tumors.

ABBREVIATIONS: SNM = sinonasal melanoma; T1-SP = septate pattern on precontrast T1-weighted MR imaging

Melanoma of the sinonasal tract roughly accounts for <1% of all melanomas and up to 4% of all sinonasal malignancies.1–5 According to the Surveillance, Epidemiology, and End Results data base, the approximate incidence of mucosal melanoma of the head and neck was 0.6–1.2 cases per million persons per year from 1987 to 2009 in the United States.6 Of these, 72.6% of patients had disease in the sinonasal location.6 The incidence of mucosal melanoma appears to be increasing, especially in the sinonasal tract.6,7

Previous studies described high signal intensity on T1WI and low signal intensity on T2WI as the characteristic MR imaging features of melanoma. The signal characteristics on MR images are attributed to the paramagnetic properties of melanin pigment.8–13 However, several substances besides melanin, such as hemorrhage, high proteinaceous secretions, and fungus can also generate high signal intensity on T1WI.12,14 In some respects, sinonasal melanoma (SNM) is distinct from other malignant sinonasal tumors. First, the prognosis of SNM is reportedly much worse than other malignant sinonasal tumors,15–17 with its overall 5-year survival rates being estimated at <30% in most series,1 while those of other sinonasal malignancies range from 22% to 67%, with an average of 45.5%.16 Since 2010, the American Joint Committee on Cancer has created a separate system for staging mucosal melanoma of the head and neck, in which a primary tumor limited to the mucosa is considered T3, which reflects the aggressive biologic behavior of the tumor.18 Second, SNM
malignant sinonasal tumors. Aging (T1-SP) for distinguishing SNMs from nonmelanomatous tumors have intrinsic high signal intensity, only A demonstrates a regular pattern of the alternating hyperintense and hypointense striations, so-called T1-SP (arrows). In contrast, the high signal intensity in B appears amorphous without the alternating hyperintense and hypointense striations in a regular pattern (asterisks).

Third, promising results are constantly being reported on the efficacy of targeted therapy for treating advanced SNMs, including biochemotherapy using cytotoxic chemotherapy and biologic immunomodulatory agents such as interferon α and interleukin 2,3,20,21. The purpose of this study was to evaluate the diagnostic value of the septate pattern on precontrast T1-weighted MR imaging (T1-SP) for distinguishing SNMs from nonmelanomatous malignant sinonasal tumors.

**MATERIALS AND METHODS**

**Patients**

This study was approved by the institutional review board at Samsung Medical Center, and informed consent was waived in accordance with the requirements of a retrospective study.

Between January 1998 and January 2015, a search of the electronic medical records of our hospital revealed 56 patients (male/female ratio = 34:22; mean age, 62 years; range, 21–88 years) with histologically proved SNM, among whom MR imaging was performed in 35. Four patients were excluded from the study because no mass could be localized on MR images, resulting in 31 patients who were subjects of this study. There were 18 men and 13 women ranging in age from 37 to 88 years (mean age, 64 years).

To validate the role of T1-SP for diagnosing SNMs, we selected MR images of 106 adult patients with 16 different types of nonmelanomatous malignant sinonasal tumors through a search of the electronic data base of our institution between January 2010 and December 2014 using the keywords “malignant tumor of the nose and paranasal sinuses.” All tumors were diagnosed histologically by biopsy and/or an operation. These 106 patients consisted of 63 males and 43 females with ages ranging from 14 to 87 years (mean age, 56 years). Table 1 demonstrates the pathologic subtypes, of which squamous cell carcinoma was most common (n = 45), followed by lymphoma (n = 22), adenoid cystic carcinoma (n = 10), and other sinonasal malignancies (n = 29).

**MR Imaging**

MR imaging examinations were performed on a 1.5T (Signa Advantage or Horizon; GE Healthcare, Milwaukee, Wisconsin) or 3T (Intera Achieva; Philips Healthcare, Best, the Netherlands) scanner. In all patients, precontrast spin-echo T1WI (TR/TE/NEX, 400–560 ms/10–14 ms/1) with or without fat saturation were obtained, followed by contrast-enhanced spin-echo T1WI with fat saturation after the intravenous injection of 0.1 mmol/kg of gadolinium-based contrast material. Images were obtained in at least 2 planes with 3- to 4-mm section thickness and 0- to 1-mm intersection gap.

**Image Analysis**

All MR images were evaluated by 3 radiologists with 4, 2, and 2 years of experience in neuroradiology, respectively, in an anonymized and randomized manner. All reviewers were blinded to the final histologic diagnosis. We evaluated the general MR imaging features of SNMs, such as the signal intensity and enhancement pattern. We determined the presence or absence of a T1-SP on MR imaging in 31 SNMs and 106 nonmelanomatous malignant sinonasal tumors. A T1-SP was determined to be present if a regular pattern of the alternating hyperintense and hypointense striations was distributed partially or diffusely within the solid components of the tumor on unenhanced T1WI (Fig 1A). Hyperintense foci without a regular pattern of alternating striations were not considered a T1-SP (Fig 1B). Before image review, the observers were instructed and tested on the imaging appearance.

**FIG 1.** Two different types of SNM containing high signal intensity on T1WI with the presence (A) or absence (B) of a T1-SP. Although both tumors have intrinsic high signal intensity, only A demonstrates a regular pattern of the alternating hyperintense and hypointense striations, so-called T1-SP (arrows). In contrast, the high signal intensity in B appears amorphous without the alternating hyperintense and hypointense striations in a regular pattern (asterisks).
of a T1-SP. MR imaging interpretation proceeded in 2 ways: First, each observer independently reviewed the images in a randomized fashion; and second, the 3 observers reached a consensus by a joint interpretation that followed individual interpretation 1 month later to minimize recall bias.

**Histopathologic Evaluation**

Histopathologic slides were available for review in 23 of 31 SNMs. A board-certified pathologist with 30 years of experience in head and neck pathology retrospectively re-examined the pathologic slides with special attention to the presence or absence of melanin, the presence or absence of intratumoral hemorrhage, and the predominant cell type. The tumors were grouped into melanotic and amelanotic tumors with the former being further categorized as those with abundant melanin when the melanin-containing cells exceeded 10% of tumor cells and those with a moderate amount of melanin when they composed <10%. Finally, we tried to identify the histopathologic features responsible for T1-SP.

**Statistical Analysis**

On the basis of the observations made by each observer, interobserver agreement among 3 observers was evaluated by calculating κ statistics. A κ value ≤ 0.20 indicated positive but poor agreement; 0.21–0.40, fair agreement; 0.41–0.60, moderate agreement; 0.61–0.80, good agreement; and ≥ 0.81, excellent agreement. On the basis of the results made by the 3 observers’ consensus interpretations, the statistical difference of a T1-SP between SNMs and other malignant sinonasal tumors was analyzed using the Fisher exact test. We also determined the overall sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of a T1-SP as the diagnostic indicator of SNM. The statistical differences in the prevalence of a T1-SP were sought according to the presence or absence of melanin, the presence or absence of hemorrhage, and the different cell types using the χ² test. During statistical analysis, differences of P < .05 were considered statistically significant.

**RESULTS**

Compared with the brain stem, 26 of 31 SNMs showed heterogeneous isointense and hyperintense signal intensity on T1WI, while 5 tumors demonstrated homogeneous hypointense (n = 1) or heterogeneous isointense and hypointense (n = 4) signal intensity. Various signal intensities were demonstrated on T2WI, including heterogeneous isointense and hypointense signal intensity (n = 15), heterogeneous isointense and hyperintense signal intensity (n = 9), and heterogeneous hypointense and hyperintense signal intensity (n = 7). Twenty-seven tumors were generally well-enhanced on contrast-enhanced T1WI, while the remaining 4 tumors showed poor enhancement. Only 2 tumors demonstrated intratumoral necrosis.

**Comparison of the Prevalences of T1-SP between SNMs and Other Malignant Tumors**

On the basis of the results of individual and consensus interpretations, we summarized the prevalences of a T1-SP in SNMs and other nonmelanomatous sinonasal malignant tumors in Tables 1 and 2. Interobserver agreement among 3 observers for the presence of a T1-SP was good, with an average κ value of 0.71.

According to a consensus reading by the 3 observers, there was a significant statistical difference in the prevalence of a T1-SP between SNMs and other malignant tumors (P < .001). Twenty-seven (87.1%) of 31 SNMs showed hyperintense foci on T1WI, among which a T1-SP was seen in 23 (74.2%), either diffusely (n = 7, Fig 2) or partially (n = 16, Fig 3). In contrast, 22 (20.8%) of 106 nonmelanomatous malignant sinonasal tumors demonstrated hyperintense foci on T1WI, among which only 3 (2.8%) showed a T1-SP. These 3 tumors included 2 of 45 squamous cell carcinomas (Fig 4A) and 1 of 14 lymphomas (Fig 4B). Overall, the sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of a T1-SP for the diagnosis of SNM were 74% (95% CI, 55%–88%), 97% (95% CI, 92%–99%), 88% (95% CI, 71%–96%), 93% (95% CI, 88%–96%), and 92% (95% CI, 83%–96%), respectively.

**Histopathologic Features of SNMs in Correlation with MR Imaging Features**

Of 23 SNMs for which retrospective histopathologic analysis was available, 18 tumors were melanotic and 5 were amelanotic. Overall, intratumoral hemorrhage was present in 14 and absent in 9.
Various histologic cell types were seen, including 15 epithelioid cell, 3 spindle cell, and 5 mixed cell types. Correlation of the histopathologic features with the MR imaging features in these 23 SNMs in terms of the presence or absence of a T1-SP is summarized in Table 3. A T1-SP was found in 14 of 18 melanotic melanomas and 4 of 5 amelanotic melanomas. Twelve of 14 tumors with intratumoral hemorrhage had a T1-SP, while 6 of 9 tumors without hemorrhage demonstrated it. There was no significant statistical difference in the prevalence of a T1-SP among tumors regarding the presence of melanin \((P = .915)\), the presence of hemorrhage \((P = .280)\), and the different cell types \((P = .399)\).

Melanin pigments were abundant in 9 of 18 melanotic tumors and moderate in the remaining 9 tumors. If melanotic tumors with moderate melanin and amelanotic tumors were grouped together, there was a significant statistical difference in the prevalence of a T1-SP between the group of tumors with no and moderate melanin and melanotic tumors with abundant melanin \((P = .043)\) using the \(\chi^2\) test, suggestive of a close relationship between the amount of melanin and the presence of T1-SP. Hemorrhage was present in 10 of 18 melanotic tumors and 4 of 5 amelanotic tumors. T1-SP was demonstrated in 1 amelanotic melanoma that had no hemorrhage on histologic examination.

Although the retrospective nature of this study kept us from performing a side-by-side MR imaging–pathologic correlation, 4 cases revealed an uneven distribution of melanin with alternating melanin and fibrous bands, which might be considered one of the pathologic features responsible for a T1-SP on MR imaging (Fig 3C, D).

**DISCUSSION**

The results of the present study are promising in that a T1-SP might be a useful imaging marker for the diagnosis of SNM with high specificity (97%) and a moderate sensitivity (74%).
(74.2%) of 31 SNMs showed a T1-SP, only 3 (2.8%) of 106 nonmelanomatous malignant tumors demonstrated it. It also proved to be reproducible, shown by good interobserver agreement.

In this study, 14 of 18 melanotic SNMs and 4 of 5 amelanotic SNMs demonstrated a T1-SP. Although we failed to reveal a significant statistical difference in the prevalence of a T1-SP between melanotic and amelanotic tumors, our results showing a significant higher prevalence of a T1-SP in SNMs compared with other nonmelanomatous tumors may still be good evidence that melanin pigment is the important source for T1-SP. In their study with 7 melanotic SMMs and 5 amelanotic SMMs, Yousem et al.11 reported that all melanotic tumors were hyperintense to gray matter on T1WI regardless of the presence of hemorrhage, while the signal intensities of all amelanotic tumors were intermediate on T1WI. They suggested that the presence of melanin should be considered the main cause of hyperintensity.11

We also failed to find any statistical significance of the prevalence of a T1-SP between hemorrhagic and nonhemorrhagic tumors and among tumors of the different cell types as well. In their study with 6 melanotic SNMs and 5 amelanotic SNMs, Kim et al9 suggested that the signal intensity of SNMs on MR imaging was affected mainly by melanin pigments but also, in part, by the hemorrhagic products. We speculate that intratumoral hemorrhage in addition to melanin should play a role in creating a T1-SP in a certain proportion of SNMs, as seen in 4 melanotic SNMs and 3 nonmelanomatous sinonasal tumors demonstrating a T1-SP in this study. Most interesting, we found an intimate relationship between the amount of melanin and the presence of a T1-SP. Although no statistical difference in the prevalence of a T1-SP was found between melanotic and amelanotic tumors, the difference was significant between tumors with abundant melanin and the group of tumors with no and moderate melanin. This finding is in accordance with the results of the study by Kim et al,9 who reported that the signal intensity pattern could vary on MR imaging depending on the amount and distribution of melanin within individual SNMs.

Previous studies also found intratumoral vessels and fibrous septa within malignant melanomas on histologic examination.9,22 We suggest that a T1-SP may be attributed to an uneven distribution of melanin and hemorrhage within the tumors. In this study, 1 amelanotic tumor without evidence of hemorrhage demonstrated a T1-SP. Although unclear, it is possible that insufficient histopathologic examination might have overlooked the presence of melanin and/or hemorrhage in this case. Although an uneven distribution of melanin with the alternating melanin and fibrous bands within the tumors seen in 4 cases in this study might be considered one of the pathologic features responsible for a T1-SP, the retrospective nature of this study interfered with an exact 1:1 MR imaging–pathologic correlation; thus, the elucidation of the exact histopathologic basis for a T1-SP was difficult. We recommend a prospective study focusing on the MR imaging–pathologic correlation in a large cohort of patients with SNM in the near future.

A T1-SP seen in an SNM in the present study looks like the convoluted cerebriform pattern seen in inverted papillomas.23 The only difference is that the former is best seen on T1WI, while the latter is seen on T2WI and contrast-enhanced T1WI. A “convoluted cerebriform pattern” is the term first used in the pathology literature by Barnes et al24 to describe a distinctive gross mucosal morphology of inverted papilloma, created by the juxtaposed epithelial and stromal layers. This peculiar mucosal morphology results in a characteristic pattern on MR imaging (ie, the alternating hypointense and hyperintense bands on T2-weighted and contrast-enhanced T1-weighted images), making the imaging diagnosis of inverted papilloma possible.23,25 Histologically, the convoluted cerebriform pattern seen in inverted papilloma is known to result from the alternation of highly cellular metaplastic epithelium and less cellular edematous stroma.25

This study has several limitations. First, the case series of SNMs is small, and the number of SNMs that underwent a histopathologic review is even smaller. Second, we used varying imaging parameters and different magnets in this study. These might alter the results of the prevalence of T1-SP because a higher magnetic field strength causes a greater sensitivity to T1 shortening. Third, the histopathologic features responsible for a T1-SP were not exactly determined because the retrospective nature of this study prevented us from performing histopathologic re-examination in all cases of SNM, making an exact 1:1 MR imaging–pathologic correlation difficult. Fourth, the proportion of SNMs included in this study is roughly 23% (31 of 137), which is much higher than up to 4% reported among all sinonasal malignant tumors. The skewed composition of the patients due to the unusually high proportion with the disease of interest can have an unreliable impact on the calculations of the diagnostic index, such as specificity, positive and negative predictive values, and accuracy and thus may not reflect the true values encountered in clinical practice.

CONCLUSIONS

Despite several limitations of this study, a T1-SP might be an adjunctive MR imaging finding for distinguishing SNM from various nonmelanomatous malignant sinonasal tumors with an overall accuracy of 92%. Although the exact histopathologic features responsible for a T1-SP are yet to be determined, we suggest that it may be attributed to an uneven distribution of melanin and hemorrhage within the tumors. A prospective study focusing on the MR imaging–pathologic correlation is highly recommended.
