ABSTRACT

BACKGROUND AND PURPOSE: Internal carotid dissection is a frequent cause of ischemic stroke in young adults. It may cause tandem occlusions in which cervical carotid obstruction is associated with intracranial proximal vessel occlusion. To date, no consensus has emerged concerning endovascular treatment strategy. Our aim was to evaluate our endovascular “distal-to-proximal” strategy in the treatment of this stroke subtype in the first large multicentric cohort.

MATERIALS AND METHODS: Prospectively managed stroke data bases from 2 separate centers were retrospectively studied between 2009 and 2014 for records of tandem occlusions related to internal carotid dissection. Atheromatous tandem occlusions were excluded. The first step in the revascularization procedure was intracranial thrombectomy. Then, cervical carotid stent placement was performed depending on the functionality of the circle of Willis and the persistence of residual cervical ICA occlusion, severe stenosis, or thrombus apposition. Efficiency, complications, and radiologic and clinical outcomes were recorded.

RESULTS: Thirty-four patients presenting with tandem occlusion stroke secondary to internal carotid dissection were treated during the study period. The mean age was 52.5 years, the mean initial NIHSS score was 17.29 ± 6.23, and the mean delay between onset and groin puncture was 3.58 ± 1.1 hours. Recanalization TICI 2b/3 was obtained in 21 cases (62%). Fifteen patients underwent cervical carotid stent placement. There was no recurrence of ipsilateral stroke in the nonstented subgroup. Twenty-one patients (67.65%) had a favorable clinical outcome after 3 months.

CONCLUSIONS: Endovascular treatment of internal carotid dissection–related tandem occlusion stroke using the distal-to-proximal recanalization strategy appears to be feasible, with low complication rates and considerable rates of successful recanalization.

ABBREVIATIONS: ICD – internal carotid dissection; sICH – symptomatic intracranial hemorrhage

A

acute obstruction or occlusion of the extracranial ICA and additional intracranial ICA or MCA thrombus, so-called tandem occlusion, causes a severe form of ischemic stroke, which accounts for 10%–20% of major strokes and is associated with high rates of disability and death.1,2 Most stenotic or occlusive lesions of the ICA are caused by atherosclerotic disease or acute dissection. These 2 pathologies constitute distinct stroke etiologies that affect 2 different patient populations, each with their own prognosis. Internal carotid dissection (ICD) is a frequent cause of ischemic stroke, especially in young adults.3 In cervical carotid occlusive or near-occlusive disease, stroke is due to wall hematoma, accompanied by downstream intracranial embolus or hemodynamic impairment.4

Tandem occlusion stroke was known to have a very poor prognosis at the time when treatment consisted of intravenous thrombolysis alone.2,5,6 Endovascular treatment is now increasingly performed following the results from recent randomized controlled trials (Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands [MR CLEAN], Endovascular Treatment for Small Core and Proximal Occlusion Ischemic Stroke [ESCAPE], Extending the Time for Thrombolysis in Emergency Neurological Deficits-Intra-Arterial [EXTEND IA], Endovascular Revascularization With Soli-
taire Device Versus Best Medical Therapy in Anterior Circulation Stroke Within 8 Hours [REVASCAT], Solitaire With the Intention For Thrombectomy as Primary Endovascular Treatment for Acute Ischemic Stroke [SWIFT PRIME], and DWI or CTP Assessment with Clinical Mismatch in the Triage of Wake Up and Late Presenting Strokes Undergoing Neurointervention with Trevo [DAWN]),\(^2\)\(^2\)\(^1\) which demonstrated the superiority of combined endovascular strategies over stand-alone intravenous treatment in large-vessel occlusion stroke. Endovascular strategies, however, remain understudied in the specific setting of tandem occlusions and were even excluded from some thrombectomy clinical trials, such as ESCAPE and SWIFT PRIME.\(^7\)\(^8\) Of several endovascular strategies that have been proposed during the past few years, the “proximal-to-distal” approach (the so-called antegrade approach) has been predominant.\(^1\)\(^3\)-\(^2\)\(^1\) It consists of stepwise treatment of the arterial occlusion, starting from the cervical internal carotid lesion and finishing with the intracranial occlusion. We propose a different approach, the “distal-to-proximal” approach, in which the intracranial occlusion is treated first to quickly restore cerebral blood flow. Then, treatment of the internal carotid cervical dissection is performed, depending on functionality of the circle of Willis and persistence of an occlusive dissection. This method had previously demonstrated promising results.\(^2\)\(^2\)

The present study describes the technical and clinical results of the first multicenter study evaluating the distal-to-proximal endovascular approach in cases of tandem occlusion related to ICD.

**MATERIALS AND METHODS**

**Sample**
Records of all patients presenting with anterior circulation ischemic stroke treated with an endovascular approach in 2 separate institutions between August 2009 and April 2013 (Montpellier) and January 2010 and September 2014 (Bern) were retrospectively retrieved from prospectively maintained stroke data bases.

**Patient Selection**
Endovascular therapy was performed immediately after CT or MR imaging under the following conditions: 1) Diagnosis of ischemic stroke was established by CT/CTA/CT perfusion or MR/MRA/MR perfusion imaging; 2) the baseline NIHSS score was ≥4, or isolated aphasia or hemianopia was present; 3) hemorrhage had been excluded by cranial CT or MR imaging; 4) symptom duration was not longer than 24 hours; 5) no individual clinical or premorbid conditions or laboratory findings contraindicated treatment; and 6) tandem occlusion of the carotid-T or M1/M2 segment associated with cervical ICA obstruction or occlusion related to cervical ICA dissection was demonstrated by initial imaging and/or peri-interventional angiograms.

**Decision-Making and Imaging**
Initial NIHSS and Glasgow Coma Scale scores were assessed by a neurologist. CT and MR imaging were used, depending on the protocol of the center. The routine CT imaging protocol consisted of unenhanced CT and CT angiography and CT perfusion. The routine MR imaging protocol consisted of DWI, FLAIR, T2*/SWI, contrast-enhanced MR angiography including the supra-aortic trunks, and MR perfusion imaging. If tandem occlusion was suspected on initial imaging, it was confirmed with DSA based on the morphologic aspect of the cervical segment of the internal carotid artery (Fig 1) associated with a proximal intracranial vessel occlusion (carotid termination, M1, M1–M2 junction, and/or M2 segment of the middle cerebral artery). The ICD diagnosis was based on clinical, imaging, and angiographic data. We aimed to distinguish dissection from atheromatous cervical carotid artery lesions.

**Intravenous Thrombolysis**
Intravenous thrombolysis (0.9 mg/kg; 10% of the dose as a bolus and the remainder during 60 minutes) was administered to patients within a maximum of 4.5 hours after stroke onset. Conventional clinical and laboratory inclusion and exclusion criteria for intravenous thrombolysis were applied.

**Endovascular Procedure**
Endovascular treatment was performed with the patient under general anesthesia or conscious sedation. The decision on the type of sedation was made on an individual basis by the neurologist, neuroradiologist, and anesthesiologist on call. DSA was performed via a transfemoral approach using a biplane, high-resolution angiography system. In one center (Bern, Switzerland), a 4-vessel cerebral angiography was always performed before the intervention. In the other center (Montpellier, France), it was performed after intracranial recanalization through a second femoral approach to assess collateral circulation through the circle of Willis and leptomeningeal collaterals. An 8F guiding catheter or an 8F or 9F balloon-guiding catheter (Guider Softtip XF, Boston Scientific, Fremont, California; Merci retriever, Concentric Medical, Mountain View, California) was introduced into the common carotid artery, and an angiographic run was performed to evaluate the occlusion. During this step, cervical internal carotid artery occlusion was demonstrated and eventually differentiated from carotid contrast agent stagnation related to isolated carotid termination thrombus. After we took into account both clinical data and angiographic morphology, ICD was distinguished from atheromatous occlusion.

In cases of obstruction related to cervical ICD, a 0.021-inch microcatheter (Headway microcatheter, MicroVention, Tustin, California; Prowler Select Plus microcatheter, Codman & Shurtleff, Raynham, Massachusetts) was navigated through the true lumen of the dissection over a 0.014-inch microwire (Transend 014, Stryker, Kalamazoo, Michigan; Traxcess, MicroVention; Silver-Speed-14, Covidien, Irvine, California). This maneuver was performed under flow arrest either through wedging of the guide catheter in the stenosis or inflation of the balloon-guide catheter to avoid thromboembolic events during crossing of the lesion. Once the microcatheter position in the true lumen had been confirmed distally by a careful contrast injection, an intermediate 5F guiding catheter (5MAX and 5MAX ACE Reperfusion Catheter, Penumbra, Alameda, California; Vasco + 33ASPI, Balt Extrusion, Montmorency, France) was then advanced over the microcatheter into the distal internal carotid artery. After we crossed the thrombus over the microwire with the microcatheter, mechanical thrombectomy was performed with a Solitaire FR (Covidien) or Trevo stent (Stryker). The thrombectomy maneuver was also per-
formed under flow arrest and manual aspiration through the intermediate catheter to prevent clot fragmentation and distal embolism. As an alternative access technique, the stent retriever was deployed first through the microcatheter; then, the intermediate catheter was advanced over the pusher wire of the stent retriever using the stent retriever as an intracranial anchor (so-called anchoring technique) to gain intracranial access with the intermediate catheter, especially in cases with very tortuous anatomy.

The result of intracranial recanalization was evaluated using the TICI score. Successful recanalization was defined as TICI 2b or 3. If intracranial recanalization was achieved, treatment of the cervical carotid dissection was left to the discretion of the operator, taking into account the functionality of the circle of Willis, residual cervical occlusion/severe stenosis or thrombus apposition, and difficulty of the endovascular access.

The 0.014-inch microwire was introduced into the petrous segment of the carotid artery to preserve distal access to the true arterial lumen for cervical stent placement. In 1 center (Bern, Switzerland), a filter protection device (FilterWire EZ; Boston Scientific) was placed distal to the dissection when anatomically possible. Then, the guiding catheter and the intermediate catheter were retrieved into the common carotid artery. A 250- to 500-mg bolus of aspirin was administered intravenously before stent placement. Cervical carotid artery stent placement was performed using the carotid Wallstent (Boston Scientific), Precise (Cordis, Fremont, California), Cristallo Ideale (Medtronic, Roncadelle, Italy), or, in case of distal cervical carotid dissection, the LEO (Balt Extrusion), Enterprise (Codman & Shurtleff), or Wingspan (Stryker) stent. Appropriate positioning and opening of the stent were immediately assessed angiographically, and additional angioplasty was performed if necessary. Several stents were used if the dissection was extensive and occlusive in the upper cervical and pre-petrous segments.

Follow-Up

Follow-up CT or MR imaging was performed 24 hours after the acute therapy to assess infarction volume and hemorrhagic status. Symptomatic intracranial hemorrhage (sICH) was defined as a documented hemorrhage associated with a decline of ≥4 points in the NIHSS score. If no hemorrhage occurred, double antiplatelet therapy was initiated and continued for 3–6 months. Single antiplatelet treatment was then maintained for 1 year or life-long, depending on the protocol of the responsible center.

NIHSS was measured following recovery from the anesthetic and throughout hospitalization until discharge. Routine clinical follow-up was performed at 3 months by an independent neurologist to evaluate the patient’s recovery using the mRS. Clinical
outcome was quantified by 3-month mRS and mortality. Favorable outcome was defined as a mRS ≤ 2.

RESULTS

Patient Population

Between August 2009 and April 2013 (Montpellier) and January 2010 to September 2014 (Bern), 531 patients with anterior circulation ischemic stroke were treated in the 2 institutions. Tandem occlusion stroke related to ICD was identified in 34 of these patients (12 women and 22 men). The mean age was 52.47 ± 10.25 years (range, 30–73 years), and the mean NIHSS score was 17.29 ± 6.23 (range, 4–36). A history of high blood pressure was noted in 14 patients. Except for patients with unknown symptom onset, such as wake-up strokes, the average time from symptom onset to arterial puncture was 215.8 ± 66.07 minutes (range, 142–360 minutes). Intravenous thrombolysis was performed in 21 cases (61.8%). Baseline characteristics of the population are given in Table 1. Patients with presumed atheromatous tandem occlusions were excluded from the study.

Procedural Results and Early Evolution

Thirty-three (97%) patients were treated under general anesthesia, and 1 (3%) patient, under conscious sedation. Successful intracranial recanalization (TICI 2b or 3) was achieved in 23 patients (67.65%). The mean time from onset to revascularization was 329.71 ± 128.82 minutes (range, 180–855 minutes). The mean number of stent retriever passes was 2.03 (range, 1–4).

In our population of patients with ICD, 15 (44.12%) finally required cervical internal carotid stent deployment. Stent placement was technically feasible in all cases, and no distal thromboembolic events were associated with stent placement. Among the stented patient subgroup (n = 15), intracranial recanalization TICI 2b–3 was achieved in 8 patients (53.3%). In the nonstented subgroup, 15 patients (78.9%) benefited from revascularization, achieving TICI 2b–3. No periprocedural complications were observed in our multicenter cohort.

Representative endovascular strategies are illustrated in Figs 1 and 2.

Two patients (5.9%) were affected by sICH. In 1 patient who received a cervical internal carotid artery stent, sICH in the basal ganglia occurred early despite a TICI 3 recanalization. Nevertheless, the patient had a favorable outcome with an mRS of 2 after 3 months. In the second patient, severe intracranial hemorrhage occurred early on while the patient was in the intensive care unit after unsuccessful mechanical revascularization (TICI 1) without cervical carotid artery stent placement, resulting in a mRS of 4 at 3-month follow-up.

Clinical Assessment after 3 Months

After 3 months, 23 (67.65%) of the 34 patients treated for ICD tandem occlusion demonstrated a favorable outcome (7 patients with mRS = 0; seven with mRS = 1; nine with mRS = 2).
Ischemic strokes due to a tandem occlusion caused by either atherosomatous disease or a carotid dissection, if untreated, commonly have a poor prognosis and clinical outcome. Before the emergence of endovascular treatment, a very modest efficacy of intravenous thrombolysis was reported in the treatment of tandem occlusion. Linfante et al reported a very low rate of 31% recanalization on late 3-day imaging follow-up. Engelert et al reported a 36% rate of good outcome after intravenous thrombolysis was reported in the treatment of tandem occlusion. In the subgroup of patients who underwent ICA stent placement, 10 (66.7%) had mRS ≤ 2 at 3-month follow-up. In the unstented subgroup, 13 patients (68.4%) had a satisfactory clinical outcome. No stroke recurrence was observed in either of the subgroups.

The clinical results are summarized in Table 2 and the On-line Table.

**DISCUSSION**

Ischemic strokes due to a tandem occlusion caused by either atherosomatous disease or a carotid dissection, if untreated, commonly have a poor prognosis and clinical outcome. Before the emergence of endovascular treatment, a very modest efficacy of intravenous thrombolysis was reported in the treatment of tandem occlusion. Linfante et al reported a very low rate of 31% recanalization on late 3-day imaging follow-up. Engelert et al reported a 36% rate of good outcome after intravenous thrombolysis was reported in the treatment of tandem occlusion. In the subgroup of patients who underwent ICA stent placement, 10 (66.7%) had mRS ≤ 2 at 3-month follow-up. In the unstented subgroup, 13 patients (68.4%) had a satisfactory clinical outcome. No stroke recurrence was observed in either of the subgroups.

The clinical results are summarized in Table 2 and the On-line Table.

**Note:** Stentriever is trademarked technology of Stryker (Trevo).

Our approach is to focus first on intracranial recanalization. This shortens the duration of cerebral ischemia. The first step consists of navigating through the cervical carotid artery lesion up to the distal segments of the ICA. Avoiding the false lumen of the dissected vessel represents the main challenge. In our experience, it has never been impossible to reach the intracranial ICA via the true lumen. We routinely use a triaxial approach. If one positions the intermediate catheter beyond the dissection, the cervical occlusion is only crossed once to perform intracranial thrombectomy. This limits the maneuvers at the level of the dissected portion of the ICA, reducing the duration of the procedure and complication risk.

Our endovascular strategy also avoids cervical ICA stent placement in a significant number of cases. In our study population, the decision about stent placement was made taking into account cervical ICA residual steno-occlusion, circle of Willis functionality, intracranial recanalization TICI grade, and pretherapeutic infarct volume based on imaging. In many cases, after we navigated inside the dissected ICA through the true lumen, this simple maneuver was sufficient to reopen the ICA lumen enough to obtain efficient blood flow. In these cases, no further stent placement procedure of the ICA was required. Then, depending on circle of Willis functionality, we did not systematically stented the cervical ICA. When there was a likelihood that stent placement would be technically difficult and/or a high risk of hemorrhage due to antiplatelet therapy because of large cerebral infarct volume, we specifically studied circle of Willis functionality. Using previously published angiographic features demonstrating the functionality of the circle of Willis, we could decide not to stent the ICA if there was an efficient vascular supply from the contralateral ICA through the anterior or posterior communicating artery or leptomeningeal collaterals. Those 2 considerations leading to the decision not to stent the dissected ICA are supported by the low rate of delayed stroke recurrence after ICD. In the present study, no patient in the nonstented subgroup had a recurrence. Therefore, treatment of ICD by stent placement in tandem occlusion in patients with acute stroke should be carefully weighed in the light of the potentially benign course of the disease under conservative management and taking into account clinical and angiographic information in decision-making.

The sICH rate of only 2 cases (5.9%) was low. In the first case, the patient benefited from complete intracranial recanalization and cervical ICA stent placement. He presented with a favorable neurologic outcome (mRS, 2 after 3 months). In the second patient, sICH was likely related to extended cerebral infarction after...
failure of endovascular treatment (TICI score = 1), leading to a poor clinical outcome (mRS, 4 after 3 months).

Despite several limits of the present study, such as its retrospective nature, it is the largest study to date dealing with the endovascular treatment of acute stroke related to tandem occlusions due to ICD using the distal-to-proximal recanalization strategy. We also present the first reported multicenter experience with the recanalization treatment of this specific stroke subtype.

CONCLUSIONS

Endovascular treatment of ICD-related tandem occlusion stroke using the distal-to-proximal recanalization strategy appears feasible, with low complication rates and considerable rates of successful recanalization. This endovascular approach prioritizes the restoration of intracranial blood flow and focuses on making an informed decision about the need for stent placement of the cervical ICA. The decision should take into account clinical and angiographic information such as the degree of intracranial recanalization, dissection extent, infarct volume on initial imaging, and the functionality of the circle of Willis.
