Segmentation of the Globus Pallidus Internus Using Probabilistic Diffusion Tractography for Deep Brain Stimulation Targeting in Parkinson Disease

ABSTRACT

BACKGROUND AND PURPOSE: Although globus pallidus internus deep brain stimulation is a widely accepted treatment for Parkinson disease, there is persistent variability in outcomes that is not yet fully understood. In this pilot study, we aimed to investigate the potential role of globus pallidus internus segmentation using probabilistic tractography as a supplement to traditional targeting methods.

MATERIALS AND METHODS: Eleven patients undergoing globus pallidus internus deep brain stimulation were included in this retrospective analysis. Using multidirection diffusion-weighted MR imaging, we performed probabilistic tractography at all individual globus pallidus internus voxels. Each globus pallidus internus voxel was then assigned to the ROI with the greatest number of propagated paths. On the basis of deep brain stimulation programming settings, the volume of tissue activated was generated for each patient using a finite element method solution. For each patient, the volume of tissue activated within each of the 10 segmented globus pallidus internus regions was calculated and examined for association with a change in the Unified Parkinson Disease Rating Scale, Part III score before and after treatment.

RESULTS: Increasing volume of tissue activated was most strongly correlated with a change in the Unified Parkinson Disease Rating Scale, Part III score for the primary motor region (Spearman $r = 0.74$, $P = .010$), followed by the supplementary motor area/premotor cortex (Spearman $r = 0.47$, $P = .15$).

CONCLUSIONS: In this pilot study, we assessed a novel method of segmentation of the globus pallidus internus based on probabilistic tractography as a supplement to traditional targeting methods. Our results suggest that our method may be an independent predictor of deep brain stimulation outcome, and evaluation of a larger cohort or prospective study is warranted to validate these findings.

ABBREVIATIONS: DBS = deep brain stimulation; FGATIR = fast gray matter acquisition T1 inversion recovery; GPe = globus pallidus externus; GPi = globus pallidus internus; M1 = primary motor cortex; MNI = Montreal Neurological Institute; PD = Parkinson disease; SMA/PMC = supplementary motor area/premotor cortex; SN = substantia nigra; STN = subthalamic nucleus; UPDRS III = Unified Parkinson Disease Rating Scale, Part III; VTA = volume of tissue activated
Materials and Methods
The use of the study data was approved by the University of Florida institutional review board. The study design was a retrospective analysis of consecutive patients with the diagnosis of PD undergoing GPi-DBS who had undergone multidirectional diffusion-weighted MR imaging as part of their preoperative targeting MR imaging. Seventeen such patients were identified. Six patients were excluded from further analysis (1 patient had bilateral DBS leads placed with no Unified Parkinson Disease Rating Scale, Part III [UPDRS III] score recorded between lead placements, 1 patient did not have the needed raw diffusion data archived, 2 patients had inadequate postoperative imaging for lead localization, and 2 patients had excessive head motion). Eleven patients underwent further analysis. Three of the 11 patients underwent bilateral lead placement at 2 separate time points. For these 3 patients, only the information obtained from the first lead placement was used in this study to satisfy the statistical assumption of independent measurements.

Chart Review
A retrospective chart review was conducted for the collection of relevant clinical and demographic data. Demographic and disease information collected included age at DBS, sex, disease duration, and handedness. Each patient’s most effective stimulation settings were also recorded. Settings were initially determined to maximize symptom control and minimize stimulation-induced adverse effects. The most common adverse effects were pulling of the contralateral arm and/or leg due to stimulation of the posterior limb of the internal capsule when the deeper contacts were used in some patients. The UPDRS III score was measured at the preoperative visit and the 6-month follow-up; change in the UPDRS III score (preoperative minus 6-month follow-up) was calculated and was the primary outcome measure of the study. Tremor-suppressing medications were held stable at the preoperative optimized dose for the duration of the study.

Image Acquisition
All patients underwent preoperative MR imaging for DBS planning. As part of the imaging protocol, patients underwent a T1-weighted MPRAGE and multidirection diffusion-weighted imaging. All scans were obtained on a 3T Verio scanner (Siemens, Erlangen, Germany) using a 12-channel head coil.

The multidirection diffusion-weighted imaging was acquired at an isotropic resolution of $1.6 \times 1.6 \times 1.6$ mm with no gap for a total of 70 slices. A total of 64 diffusion directions were acquired at a b-value of 1000 s/mm$^2$. Total imaging time was 12 minutes 14 seconds (TR = 10,800 ms, TE = 100 ms, phase partial Fourier = 5/8, generalized autocalibrating partially parallel acquisition = 2, bandwidth = 1098 Hz/Px, and EPI factor = 130).

The MPRAGE imaging was acquired in the axial plane after the administration of gadolinium-based intravenous contrast (0.1 mm/kg). Imaging parameters included an in-plane resolution of $0.6 \times 0.6$ mm with a slice thickness of 1.0 mm, TR = 1720 ms, TE = 3.29 ms, TI = 865 ms, flip angle = 9°, and bandwidth = 170 Hz/Px. Image acceleration included a 7/8 phase partial Fourier imaging and generalized autocalibrating partially parallel acquisition = 2.

Additionally, a volumetric FGATIR sequence was obtained, as previously reported, for targeting purposes.

All postoperative CT scans were obtained on an Aquilion scanner (Toshiba Medical Systems, Tokyo, Japan) using a 0.5 × 0.5 mm in-plane resolution with a slice thickness of 1 mm.

Surgical Procedure
GPi-DBS was planned contralateral to the patient’s most symptomatic upper extremity. All surgical procedures were performed by the same surgeon (K.D.F.). For targeting, brain MR imaging was acquired before the initial procedure. On the day of the operation, a Cosman-Roberts-Wells head ring was placed, and stereotactic high-resolution CT was performed. In-house software was used to fuse the CT and MR imaging data. The postcontrast T1-weighted MPRAGE and FGATIR MRI sequences were paired with a deformable brain atlas in order to identify the corpus striatum, the globus pallidus, and the optic tract anatomy. Single microelectrode recording was sequentially performed to establish the border between the globus pallidus externus (GPe) and the Gpi by the sound of the border cells. The inferior Gpi border was established by the sound of the optic tract. Macrostimulation was performed to assure the best lead position.

ROI
In contrast to the prior study in healthy controls, we limited our connectivity targets to known predominant connections of the globus pallidus internus. 13 ROIs for probabilistic tractography were defined in Montreal Neurological Institute (MNI) template space and created using the FSLview “atlas” function (https://fsl.fmrib.ox.ac.uk/fsl/fslwiki/FslView). Masks were created for the
caudate, GPe, GPi, putamen, and subthalamic nucleus (STN) from the MNI Basal Ganglia Human Area Template. The substantia nigra (SN) mask was generated using atlasing of the basal ganglia. Cortical ROIs were concatenated for the primary motor cortex (M1) and supplementary motor area and premotor cortex (SMA/PMC) from the MNI Human Motor Area Template. Masks for the prefrontal cortex and thalamus were generated from the Harvard-Oxford Cortical and Subcortical Atlases, respectively. Last, the pedunculopontine nucleus was manually drawn in MNI space to approximate the location of this poorly visualized structure within the midbrain-pontine tegmentum inferior, posterior, and lateral to the red nucleus.

Imaging Preprocessing
Diffusion data underwent standard preprocessing consisting of re-alignment and eddy current correction using the FMRIB Software Library (ISL; http://www.fmrib.ox.ac.uk/fsl). The diffusion-weighted data were normalized to the MNI_ICBM_2009b_NLINASYM atlas space (http://neuro.debian.net/pkgs/mni-icbm152-nlin-2009c.html).

Preoperative MPRAGE and postoperative CT were coregistered by a 2-stage linear registration consisting of a rigid and subsequent affine registration used in the Advanced Normalization Tools software package (http://stnava.github.io/ANTS/). Next, these volumes were also normalized to the MNI_ICBM_2009b_NLINASYM atlas space with the SyN registration approach in the Advanced Normalization Tools.

Diffusion Data Processing
Voxelwise diffusion parameters were estimated from the preprocessed diffusion data using a Markov Chain Monte Carlo sampling in the FSL BEDPOSTX (https://fsl.fmrib.ox.ac.uk/fsl/fslwiki/FDT) function. Next, probabilistic tractography was performed with PROBTRACKX2 (https://fsl.fmrib.ox.ac.uk/fsl/fslwiki/FDT) in FSL to calculate a probability of connection of each voxel within the left and right GPi masks to each of the 10 previously defined target masks. Five thousand total fiber tracks were generated with a curvature threshold = 0.2, step length = 0.5 mm, and maximum steps = 2000. Last, all GPi voxels were classified by the 1 target mask with the greatest number of propagated paths by the FSL “find_the_biggest” function.

Volume of Tissue Activated Modeling
The DBS electrodes were localized on the normalized postoperative CT using the Lead-DBS software package (http://www.lead-dbs.org). Manual corrections, when necessary, were performed to ensure the accuracy of the contact locations. Once contact locations were determined, the VTA was simulated using the patient’s most effective programming settings, as implemented in Horn et al. Briefly, a finite-element method solution was derived using a tissue-specific conductivity model. The volume of overlap between each patient’s simulated VTA and each of the 10 segments within the patient-specific GPi segmentation was calculated.

Statistical Analysis
Continuous variables were summarized with the sample median and range. Categoric variables were summarized with the number and percentage of patients. The degree of association between the VTA in each of the 10 different brain regions and the change in the UPDRS III score from preoperative to 6-month follow-up visits were evaluated by estimating the Spearman correlation coefficient r. Although Spearman tests of correlation were also performed, due to the pilot nature of the study and the corresponding small sample size, results of these tests are primarily given for completeness, and emphasis should be placed on the Spearman correlation coefficient r values when interpreting results. For brain regions in which <3 patients had a value greater than zero regarding the VTA, the Spearman correlation was not assessed because these regions were essentially noninformative due to lack of variability in measures. Associations of age and disease duration with change in the UPDRS III score were examined in a similar manner. P values ≤ .05 were considered statistically significant. All statistical tests were 2-sided. Statistical analyses were performed using SAS (Version 9.4; SAS Institute, Cary, North Carolina) and R Statistical and computing software (Version 3.2.3; http://www.r-project.org).

RESULTS
A summary of patient characteristics, DBS characteristics, and outcomes is shown in the Table. The median age at DBS was 62 years (range, 49–73 years), almost all patients were male (n = 10 [91%]), and the median disease duration was 9 years (range, 6–16 years). The median UPDRS III score was 42 (range, 27–55) before the operation and 21 (range, 13–40) at 6-month follow-up, corresponding to a median decrease of 15 (range, 12-point increase to a 31-point decrease).

Group averages for each of the 10 segmented regions are shown in Fig 1. Of the 10 GPi segments assessed, only 4 (GPe, M1, SMA/PMC, SN) had at least some VTA in >2 patients (Table and On-line Figure) and were therefore evaluated further for association with change in the UPDRS III score. For these 4 GPi segments, the VTA was most strongly correlated with change in the UPDRS III score for the segment most connected to the M1 region (Spearman r = 0.74, P = .010, Fig 2), followed by the SMA/PMC (Spearman r = 0.47, P = .15, Fig 2), GPe (Spearman r = 0.16, P = .64, Fig 2), and SN (Spearman r = 0.15, P = .67, Fig 2) regions. Of note, we did not observe a strong correlation with change in the UPDRS III score for either age at DBS (Spearman r = −0.23, P = .49) or disease duration (Spearman r = −0.08, P = .81), indicating that these 2 variables would have had minimal confounding influence on the correlations between the VTA and change in the UPDRS III score.

DISCUSSION
The GPi is considered the primary output structure of the basal ganglia and is known to have an increase in its neuronal activity before the onset of PD motor symptoms. GPI-DBS has been successfully used to abolish dyskinesias in patients with treatment-resistant hyperkinetic movements, tremor, and dystonia in PD. In this pilot study, we assessed a novel method of segmentation of the GPi based on probabilistic tractography. We found that a greater VTA in the somatosensory region of the GPi within our defined M1 segment and, to a lesser degree, the SMA/
of GPi fibers connect to the SN, arising from the medial inferior border of the GPi.34 Connections have also been illustrated between the Gpi and pedunculopontine nucleus, exiting from the medial portion of the Gpi.35-38 Along the border between the Gpi and GPe, inhibitory fibers exit the medial GPe and connect via the lateral border of the Gpi.33,34 Last, the posterolateral border of the Gpi has been shown to connect to the adjacent putamen and may produce a decrease in Gpi inhibition in PD secondary to decreased putaminal excitation.13,39,40

While many of these deep connections of the Gpi have been well-described, there has historically been little attention to direct cortical connections from the Gpi. Tracer studies in rats and monkeys, as well as human DTI studies, have demonstrated the presence of these corticopallidal fibers, particularly in relation to the prefrontal cortex, SMA, pre-SMA, primary motor, and primary sensory cortices.41-45 Additional information regarding the connectivity of the Gpi to the motor cortex (M1 region) has been elucidated from studies measuring local field potentials, where β oscillations in the range of 13–40 Hz have been recorded from the Gpi in a movement-related manner, similar to recordings noted in the primary motor cortex.46-48 Because the Gpi is the main output structure of the basal ganglia, increased excitation of this structure produces some of the hypomotor symptoms seen in PD. However, the role of these corticopallidal connections in the pathophysiology and treatment of movement disorders has not been well-investigated to date. We hypothesized that the efficacy of DBS could be secondary to suppressing the connections arising from the M1 region.

In our study, we could elucidate direct connections between the Gpi and cortex, specifically the prefrontal cortex, SMA, PMC, and M1 regions. As previously reported by Milardi et al43 using constrained spherical deconvolution, these fiber pathways are distinct from the hyperdirect pathway passing through the internal capsule. The results of this pilot study suggest that a larger VTA in the segment corresponding to dominant connectivity to the M1 region in patients with PD may be correlated with a greater improvement in the UPDRS III score. Findings were similar, though weaker, for the SMA/PMC segment, whereas no notable correlation with change in the UPDRS III score was observed for the VTA in the globus pallidus externus and SN segments. The idea that structural and functional connectivity measures represent independent outcome predictors has been previously shown in other treatment targets.8,49-51 For instance, Horn et al8 have shown that connectivity measures within the STN are potentially independent outcome predictors in DBS of PD. Most interesting, they found a positive correlation with the clinical response within the STN and connectivity to the SMA, while a negative correlation with the clinical response was found with the primary motor cortex.8 This anticorrelation between the DBS electrode and the primary motor cortex presenting in the STN, and not in Gpi, may be explained by the development of motor adverse effects, such as verbal fluency problems,52 when stimulating the M1 region in the smaller STN.

Remarkably, in contradistinction to the prior study by da Silva et al,13 we found that the posterior ventral portion of the Gpi corresponds to a corticopallidal area most connected to the primary motor cortex. The area most connected to the SMA/PMC

Note: PFC indicates prefrontal cortex; PPN, pedunculopontine nucleus.

The sample median (minimum, maximum) is given for continuous variables.

PMC segment, corresponded with greater improvement in the UPDRS III score.

The globus pallidus, with the putamen, forms the lentiform nucleus and primarily exhibits inhibitory control on movement.28 The Gpi has extensive connections to deep brain structures. A predominant output of the Gpi consists of pallidothalamic connections comprising the ansa lenticularis and lenticular fasciculus (components of the thalamic fasciculus). The ansa lenticularis and lenticular fasciculus exit the Gpi along the inferomedial and medial borders, respectively. These projections largely correspond to a corticopallidal area most connected to the primary motor cortex.
was in proximity yet slightly more ventral in the posterior GPi (Fig 3). These findings are like those reported in prior animal tracer and DTI studies. The basis for the discrepancy with the prior study is uncertain. One potential explanation is the reduction of voxel volume by greater than a factor of 3, potentially allowing better discrimination of these small areas of corticopallidal connectivity. Also, differences in the number of diffusion directions could potentially alter angular resolution, though the number of diffusion directions obtained in the prior study was not published.

Accuracy in structural and functional targeting is vital for successful deep brain stimulation. The GPi shows more variation in position relative to the midpoint of the line traversing the anterior/posterior commissure line compared with other deep nuclei. This
variation may have partly contributed to the inconsistency in outcomes of early studies of GPi-DBS. Substantial improvement in targeting by direct structural targeting, such as FGATIR MR imaging, and sophisticated targeting software using atlas overlays and a deformable brain atlas have contributed to improved anatomic targeting. The supplementation of targeting in functional neurosurgery using connectivity measures, such as DTI, is also a promising technique. Despite these advances, improvement in preoperative functional mapping within the deep nuclei is needed to maximize the benefits of direct-targeting methods.

While debate exists on the optimal target nucleus, 1 advantage of GPi stimulation versus STN is the size of the GPi, meaning a lower probability of off-target stimulation and unintended adverse effects. However, the need for a larger VTA to achieve a desired therapeutic effect in the GPi means increased energy usage and decreased battery life. Improvement in preoperative targeting by incorporating measures of connectivity may allow the maximization of the therapeutic effect within the GPi and help overcome some of these drawbacks by providing a more specific and focused treatment target. Given the lower rate of adverse stimulation effects, the GPi could become an even more attractive target.

Our study has several notable limitations. The greatest limitation is the small sample size, which results in a lack of precision of estimated correlations. Although we did identify 1 statistically significant association despite the small sample size, larger studies are needed to better elucidate the role of our methods in supplementing preoperative GPi targeting. However, the small sample size is appropriate for the pilot nature of the study. Second, the retrospective nature only allows modeling of VTAs from data that were historically recorded, limiting comparison of different stimulation parameters in each patient. Third, the role of corticopallidal connections in PD pathophysiology warrants further exploration, given the paucity of existing knowledge. Because these connections in humans have largely been described by noninvasive MR tractography, further confirmation of their existence in anatomic specimens is needed. Last, the methods used in this study inherently oversimplify the connectivity profiles of the VTA because each voxel is assigned to only the target of the most propagating paths. While this feature potentially limits the methods in understanding the pathophysiology behind GPi-DBS, the goal of this investigation was the establishment of a reliable and reproducible subject-specific functional preoperative target for GPi-DBS placement.

CONCLUSIONS

Despite advances in preoperative targeting for DBS, reproducible methods for defining subject-specific connectivity targets with the GPi are lacking. Our preliminary study has shown an independent predictive value of connectivity-based segmentation of the GPi on patient outcomes. Our clinically feasible technique may be of benefit in supplementing direct structural targeting, as well as in DBS programming, to maximize therapeutic outcomes. Larger studies will be needed to further corroborate these findings.
