Altered White Matter Microstructure in the Corpus Callosum and Its Cerebral Interhemispheric Tracts in Adolescent Idiopathic Scoliosis: Diffusion Tensor Imaging Analysis

C. Xue, L. Shi, S.C.N. Hui, D. Wang, T.P. Lam, C.-B. Ip, B.K.W. Ng, J.C.Y. Cheng, and W.C.W. Chu

ABSTRACT

BACKGROUND AND PURPOSE: Neural system was one of the important contributors to the etiopathogenesis of adolescent idiopathic scoliosis; additionally, the morphology of corpus callosum interconnecting both hemispheres of the brain was found to be altered morphologically. Our aim was to evaluate and compare the microstructural changes of the corpus callosum and its interhemispheric white matter fiber tracts interconnecting both cerebral hemispheres in patients with adolescent idiopathic scoliosis and matched controls using diffusion tensor imaging.

MATERIALS AND METHODS: Brain DTI was performed in 69 patients with adolescent idiopathic scoliosis (female, right thoracic/thoracolumbar curve) and 40 age-matched controls without adolescent idiopathic scoliosis (female). 2D and 3D segmentation of the corpus callosum were performed using a region-growing method, and the corpus callosum was further divided into 6 regions, including the rostrum, genu, anterior and posterior midbodies, isthmus, and splenium. The laterality index was calculated to quantify the asymmetry of the corpus callosum. Interhemispheric fiber tractography were performed using the Brodmann atlas.

RESULTS: 2D ROI analysis revealed reduced fractional anisotropy in the genu and splenium ($P = .075$ and $P = .024$, respectively). Consistently reduced fractional anisotropy on the left sides of the genu and splenium was also found in 3D ROI analysis ($P = .03$ and $P = .012$, respectively). The laterality index analysis revealed a pseudo-right lateralization of the corpus callosum in adolescent idiopathic scoliosis. Interhemispheric fibers via the splenium interconnecting Brodmann 3, 1, and 2; Brodmann 17; and Brodmann 18 (corresponding to the primary somatosensory cortex and primary and secondary visual cortices) were also found to have reduced fractional anisotropy ($P \leq .05$).

CONCLUSIONS: Reduced fractional anisotropy was found in the genu and splenium of the corpus callosum and corresponding interhemispheric fiber tracts interconnecting the somatosensory and visual cortices via the splenium. Our results are suggestive of altered white matter microstructure within the brain of those with adolescent idiopathic scoliosis, which could be related to abnormal brain maturation during adolescence in adolescent idiopathic scoliosis and could possibly explain the previously documented somatosensory function impairment and visuo-oculomotor dysfunction in this condition.

ABBREVIATIONS: AIS = adolescent idiopathic scoliosis; CC = corpus callosum; FA = fractional anisotropy; LI = laterality index

Adolescent idiopathic scoliosis (AIS) is the most common form of scoliosis that causes 3D structural deformities of the spine, which affect approximately 4% of teenagers during pu-

erty. AIS has been reported to involve impaired balance control,¹ possibly due to a combination of disruptive somatosensory² and visuo-oculomotor and vestibular³ functions. Multiple studies have repeatedly shown evidence of disturbed somatosensory function in AIS, with a higher percentage of abnormal cortical somatosensory-evoked potentials compared with healthy controls.^{1,2}

Apart from the neurophysiologic dysfunction, the neuromorphologic changes in AIS have been documented by various imaging studies with changes in the cord^{4,5} and brain, including low cerebellar tonsils,⁶ abnormalities in white matter density,⁷ cerebral cortical thickness,⁸ and corpus callosum (CC) morphology.^{9,10} Asymmetries in the cerebral hemispheres^{7,9,11} and vestibular apparatus¹² were also found in AIS. The neural system is proposed as one of the important contributors to the etiopathogenesis of AIS.¹³

Diffusion tensor imaging visualizes water diffusion of white matter fiber tracts.¹⁴ The fractional anisotropy (FA) value is commonly applied to interpret the altered microstructure of these tracts.¹⁴ It is highly sensitive to microstructural changes and could be used to reflect microstructural integrity such as fiber density, axonal diameter, and myelination of white matter.

A previous DTI study of the spinal cord and hindbrain showed lower FA values in the medulla oblongata and cervical spinal cord.⁴ Another DTI study by Joly et al¹⁵ found a significant decrease in FA values in the midbody of the CC, which possibly suggests abnormal brain development in AIS.

The objective of this study was to use the DTI technique in a larger subject cohort to investigate whether there is any difference in white matter microstructure within the brain between AIS and matched controls using a 3D approach. The ROI was focused on the CC because it is the largest fiber bundle and connector between the 2 cerebral hemispheres.

MATERIALS AND METHODS

Subjects

The research protocol was approved by the Clinical Research Ethics Committee of the institution and was conducted in compliance with the principles of the Declaration of Helsinki. Written informed consent was obtained from all subjects. Subjects with AIS and healthy controls (age- and sex-matched) were prospectively recruited for DTI from January 2012 to December 2014. Patients with AIS were recruited from our outpatient clinic, while the healthy controls were recruited from local schools. All participants were right-handed Chinese female adolescents 12–18 years of age. Inclusion criteria of patients with AIS were typical scoliosis curves convex to the right side. They were carefully assessed clinically to rule out other known associated causes of scoliosis and any neurologic abnormalities. Healthy controls were screened by experienced orthopedic surgeons to exclude minor scoliosis. Exclusion criteria of all subjects were a history of head or back injury, developmental delay, or psychiatric illness.

MR Imaging Acquisition

All subjects underwent MR imaging using a 3T scanner (Achieva TX series; Philip Healthcare, Best, the Netherlands) equipped with an 8-channel sensitivity encoding head coil. For the suppression of eddy current artifacts, brain sensitivity encoding–DTI was acquired using a single-shot EPI sequence with the following parameters: TR = 8667 ms, TE = 60 ms, FOV = 224 × 224 mm², flip angle = 90°, NEX = 1, matrix = 112 × 109, sections = 70, section thickness = 2 mm, no interslice gap with an in-plane image resolution = 2 × 2 mm. Thirty-two directions of diffusion gradients with b-values of 1000 s/mm² and 1 B₀ volume were collected. Conventional T1-weighted images of the brain for mapping were obtained using a 3D fast-field echo imaging sequence with following parameters: TR = 18 ms, TE = 2.4 ms, FOV = 210 × 210 mm², flip angle = 30°, NEX = 1, matrix = 232 × 232, sections = 200.

MR Image Preprocessing

The FMRIB Software Library (FSL; <http://www.fmrib.ox.ac.uk/fsl>)¹⁶ was used to perform eddy current correction and head mo-

tions correction by registering each data point to the first $b=0$ image with affine transformation. Nonbrain tissues were also excluded using the FSL Brain Extraction Tool (<http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/BET>).¹⁶ After the preprocessing methods, all data were manually checked to exclude any errors.

Voxelwise Statistical Analysis

For voxelwise statistical analysis, the Tract-Based Spatial Statistics (TBSS; <http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/TBSS>) pipeline available in FSL 5.0.9 was performed.¹⁷ First, FA maps from all participants were smoothed using Gaussian filters with the full width at half maximum of 6 mm and aligned into a 1-mm³ FA template created by aligning every FA image to every other one using the FMRIB Nonlinear Registration Tool (FNIRT; <http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/FNIRT>). Second, the mean FA image was calculated from all normalized FA images and thinned to create a mean FA skeleton, which represented the centers of all tracts common to the group. Finally, the skeleton was set to have an FA threshold of 0.2 (FA ≥ 0.2) to ensure that gray matter regions were excluded from the analyses. Resulting skeletonized data were fit into voxelwise cross-subject statistics. The FSL Randomise method (<https://fsl.fmrib.ox.ac.uk/fsl/fslwiki/Randomise>) was used with threshold-free cluster enhancement at a P value < .05 to compare the data and correct the multiple comparisons.

ROI Analysis

After we obtained the FA maps, a 2D segmentation of the CC was performed manually in the midsagittal plane as shown in Fig 1A, followed by a 3D segmentation of the same region semiautomatically using a region-growing method in the FA maps by ITK-SNAP 2.4 (www.itksnap.org).¹⁸ For consistency, all 3D segmented CCs consisted of 15 slices on either side of the midlines and the midline image (ie, 31 slices in total), which incorporated the main bulk of CCs as illustrated in Fig 1B. All segmented CCs were manually checked for correctness. Regional segmentation of CCs was performed on the basis of the template defined by Witelson,¹⁹ which included the rostrum, genu, anterior midbody, posterior midbody, isthmus, and splenium from an anterior-to-posterior direction. 3D segmentation was further divided into left (LHS) and right (RHS) sides, with the midsagittal line acting as the dividing line. The laterality index (LI)²⁰ was calculated by the following formula:

$$LI = \frac{Mean\ FA_{LHS} - Mean\ FA_{RHS}}{Mean\ FA_{LHS} + Mean\ FA_{RHS}}$$

The laterality index shows left hemispheric lateralization by the value ≥ +0.1, while the value ≤ −0.1 indicates rightward asymmetry. Values between +0.1 and −0.1 represent bilateral lateralization.²⁰

DTI Tractography Analysis

DSI Studio (<http://dsi-studio.labsolver.org/>)²¹ was used to process the corrected diffusion-weighted images for fiber tractography analysis. To measure and quantify the fiber tracking from the left to right hemisphere of the brain, we applied the Brodmann atlas,²² and the midsagittal line was used as the middle line to separate the atlas into left and right sides. The Brodmann atlas was

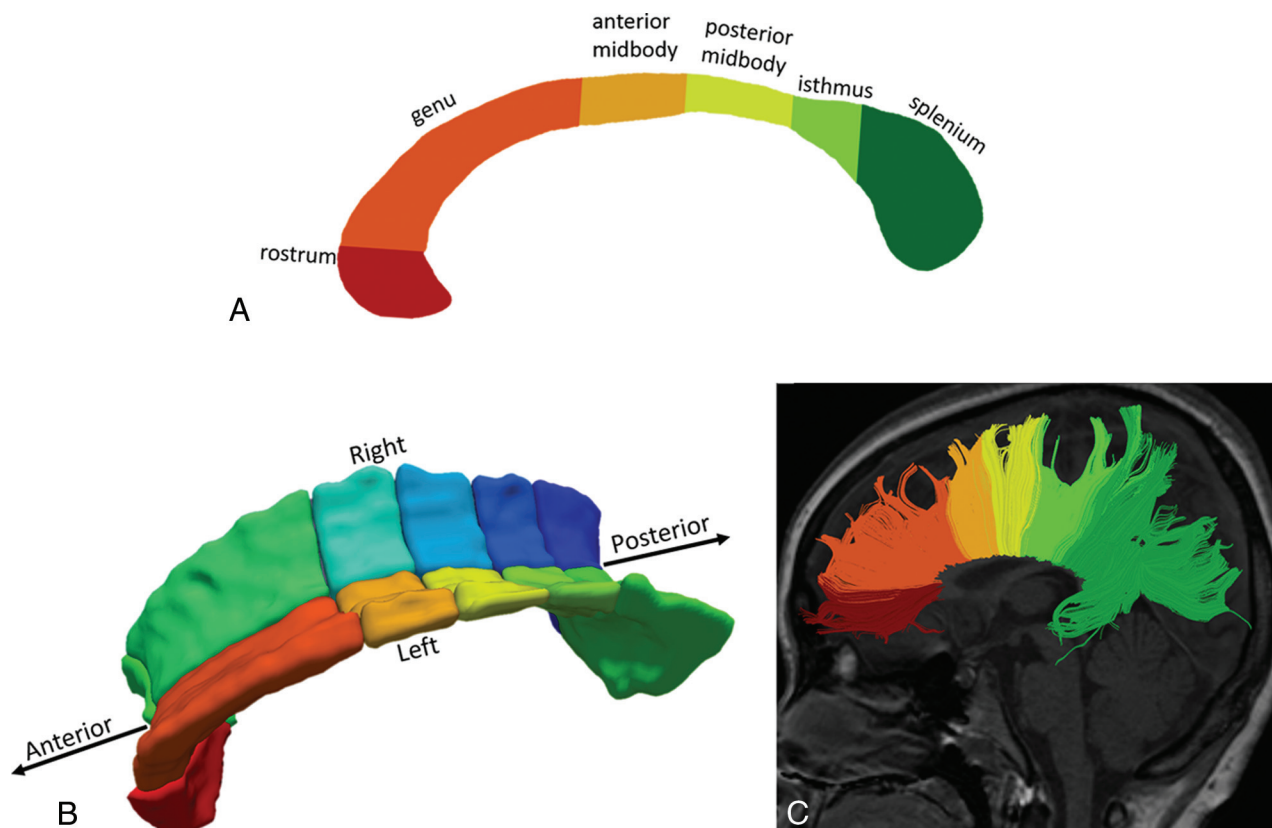

FIG 1. Subdivision of the CC based on the Witelson template¹⁹ in the midsagittal view in 2D segmentation (A), 3D segmentation (B), and fiber tractography (C).

FIG 2. Illustration of the interhemispheric tract with the ROIs (left and right Brodmann 2) selected from the Brodmann atlas.

then registered nonlinearly to the subject space using the statistical parametric mapping (SPM software; <http://www.fil.ion.ucl.ac.uk/spm/software/spm12>) nonlinear registration algorithm. For each tract, left and right ROIs were placed to establish the tract network with the following cutoffs and thresholds: FA threshold = 0.15; angular threshold = 70,²³ only limited to fibers passing through the CC as shown in Fig 2.

Statistics

The FA maps in the AIS group were compared with those in the control groups using an independent *t* test. One-way ANOVA was performed to compare mean FA values among the control and

AIS groups with different levels of severity (ie, mild, moderate, and severe) with Bonferroni as a post hoc analysis. The level of statistical significance was defined at $P \leq .05$. False discovery rate correction was used for multiple comparison corrections.

RESULTS

Participant Characteristics

Sixty-nine right-handed patients with AIS (female; mean age, 14.5 ± 2.2 years; mean Cobb angle, $33.55^\circ \pm 13.9^\circ$) and 40 age-matched right-handed healthy controls (female; mean age, 14.6 ± 1.04 years) were recruited. The AIS group consisted of 65 patients with a dominant right thoracic curve and 4 patients with a dom-

Table 1: Demographics of subjects with AIS with different curve severities and healthy controls

inant right thoracolumbar curve. Their demography is shown in Table 1.

The 69 patients with AIS were further divided into 3 groups based on the severity of their scoliosis curve defined by the Cobb angle as follows: mild group ($n = 9$, Cobb angle = 13°–19°); moderate group ($n = 43$, Cobb angle = 20°–39°); and severe group ($n = 17$, Cobb angle = 40°–79°).⁵ T1- and T2-weighted images were reviewed by an experienced radiologist (W.C.W.C.), and no structural brain abnormality was found in any subject.

Voxel-Based Analysis

Using the TBSS analysis implemented in FSL, we found no significant lower FA ($P = .438$) between the 2 groups voxelwise, even though slightly lower mean FAs were found in the splenium of patients (Fig 3).

2D ROI Analysis of the Corpus Callosum

The summary of FA values at different regions of the CC from 2D analysis is shown in Fig 4. Significantly lower mean FA values in patients with AIS were found in the genu (uncorrected $P = .025$) and splenium (uncorrected $P = .004$). Compared with different scoliosis severities, significantly lower FA values were found only in the splenium (corrected $P = .02$), while a marginal difference (corrected $P = .069$) of lower FA values was observed in the genu when we compared the control with the moderate group. After multiple comparison correction, significantly reduced FA values were persistently found in the splenium of patients with AIS (corrected $P = .024$). The overall summary is shown in Table 2.

3D ROI Analysis of the Corpus Callosum

Using 3D segmentation, we performed analysis of the CC in detail with data obtained from the whole region instead of only 1 mid-sagittal slice in 2D. We also conducted the left-right comparison, which was not performed in the previous 2D study.¹⁵

FA values were compared between the left and right sides of the CC, summarized in Fig 5 and Table 3. Lower FA values were found significantly on the left side of splenium (corrected $P =$

.012) and in the left genu (corrected $P = .03$). Comparisons among different severities of AIS revealed significantly lower FA values on the left side of the splenium (corrected $P = .048$) and genu (corrected $P = .012$) in the moderate group. FA values from the left side of the splenium (corrected $P = .078$) also showed a trend toward lower values in the severe group.

The LI assessed lateralization of the brain. Comparison between controls and patients with AIS is shown in Fig 6

and Table 4. Results indicated that LI values in different regions of the CC of both those with AIS and controls fell between +0.1 and –0.1, compatible with bilateral lateralization in both subject groups, however, with a significantly lower LI in the splenium of the corpus callosum (corrected $P = .012$) and in the genu (corrected $P = .03$) of those with AIS. The above findings reflected significant interhemispheric FA asymmetry of the CC with reduced FA on the left side (pseudo-right lateralization) in AIS compared with controls. This pseudo-right lateralization was also significant (corrected $P < .05$) when comparing controls with the moderate AIS group.

DTI Tractography Analysis

The mean FA values of all the resulting tracts were extracted and compared between patients with AIS and controls. Significantly lower FA values were only observed in Brodmann 3, 1, and 2, with mean FA values of 0.517 (AIS) versus 0.53 (controls) ($P = .045$), which reflect the primary somatosensory cortex; Brodmann 17 with mean FA values of 0.567 (AIS) versus 0.581 (controls) ($P = .027$); and Brodmann 18 with mean FA values 0.571 (AIS) versus 0.582 (controls) ($P = .038$), which are correlated with the primary visual cortex (V1) and secondary visual cortex (V2), correspondingly, in AIS. When we compared patients with AIS with different severities, lower FA values were also detected in Brodmann 17 with a mean FA value of 0.563 ($P = .007$) and Brodmann 18 with a mean FA value of 0.5693 ($P = .029$) in moderate cases.

DISCUSSION

The corpus callosum is known as the largest white matter fiber bundle connecting both hemispheres of the brain.²⁴ Different segments of the CC are connected to different cerebral regions²⁴ as shown in Fig 1C. Topographic organization of the CC is supported by various studies^{25,26} in patients with surgical resection of callosal lesions: Anterior callosal axons transfer motor information between frontal lobes, while posterior fibers crossing the posterior midbody, isthmus, and splenium transfer somatic sensory, auditory, and visual information.²⁶

^b P value after multiple comparison correction.

In our 2D ROI analysis, significantly lower FA values were found in the genu and splenium. In 3D ROI analysis, significantly lower FA values at the left genu and left splenium were consistently found as in the 2D ROI analysis, while in the study of Joly et al,¹⁵ lower FA values were found in the midbody. The above apparent discrepancies could be partially explained by different templates used in dividing the CC. The genu in this study overlapped the anterior midbody in the study of Joly et al. Hence, both studies were basically in agreement; however, an additional area of lower FA value was found in the splenium of patients with AIS in the current study, which might be partially explained by differences in subject recruitment. Our study included a larger number of patients with AIS with major right thoracic curves while in the study of Joly et al, subjects predominantly had major thoracolumbar curves.

The genu of the CC provides interconnection to the prefrontal cortex, premotor cortex, and supplementary motor area.²⁴ Caille et al²⁵ studied patients without epilepsy with resection of different portions of the anterior CC, showing that motor coordination transfer occurred at the level of the middle portion of the genu. Our study showed a significantly lower FA value and reduced laterality index in the genu of patients with AIS, which concurs with previous fMRI findings about an abnormal activation in the supplementary motor area and a significantly higher interhemispheric asymmetry index in the premotor cortex and supplementary motor area in patients with AIS.²⁷

Our tractography analysis found lower FA values in the fibers passing through the splenium and interconnecting primary

somatosensory cortex (Brodmann 3, 1, and 2) and the primary and secondary visual cortices (Brodmann 17 and 18) in patients with AIS. Fabri et al²⁸ performed an fMRI study in a human subject who had undergone resection of the CC (callosotomy) in 2 stages and concluded that integrity of the posterior body of the CC/splenium was required for normal interhemispheric transfer of somatosensory input to activate the related cerebral cortex. In the current

study, we found significantly lower FA values on the left side of the splenium after multiple corrections. Our findings correspond with the clinical observation of somatosensory-evoked-potential dysfunction in AIS.^{1,2,29} According to the study of Fabri et al,²⁸ for subjects with an intact posterior body of the CC, peripheral somatosensory stimulation leads to activation of both contralateral and ipsilateral somatosensory areas and the posterior parietal cortex; however, if the posterior half and splenium of the CC was damaged, activation could only be observed in the contralateral cortex. In this study, lower FA was found on the left side, which corresponded to the reported somatosensory-evoked-potential abnormalities²⁹ found over the right cerebral cortex in patients with AIS with a typical right thoracic scoliotic curve.

Other reported studies have provided evidence that transfer of visual^{30,31} information between the hemispheres occurs in the splenium. Our finding of reduced FA values in fibers interconnecting the visual cortex coincides with findings of a previous study in which smaller brain volume closely related to the visual cortex was found in patients with AIS.⁹ Moreover, visually impaired children have been shown to have a higher risk of spinal deformity.³²

What is the possible link between such alterations of the CC and scoliosis development in AIS? The human brain develops extensively during adolescence, with maturation of the CC continuing until early adulthood,³³ characterized by both myelination and axonal pruning; hence, development of the brain could be reflected by FA values in DTI because it reveals information

about the homogeneity of water diffusion. Different regions of the CC mature at different pubertal stages.³⁴ Both the genu and splenium become more mature and thicker, reaching 90% of maximal thickness in earlier puberty,³⁴ which coincides with the typical period for the onset of the scoliotic curve in AIS. Burwell et al³⁵ have formulated a collective model of the pathogenesis of AIS, which is a neuro-osseous timing of the maturation system operating in a child's internal world during growth and maturation. Burwell et al have suggested that AIS progresses as the neural system fails to maintain a balance of postural equilibrium to con-

trol asymmetric growth of a rapidly enlarging and moving adolescent spine. In line with the above theory, we hypothesize that the brain maturation process, including the maturation of the genu and splenium in AIS, might be interrupted during the rapid growing period of adolescence when onset and/or progression of the scoliotic curve occurs. Our finding has suggested that there are alterations of white matter in the CC reflected by lower FA values. These alterations are also in agreement with previously reported morphologic changes of the CC by MR imaging.^{9,10}

Furthermore, we found reduced FA on the left side of the CC

^c Statistically significant ($P < .05$).

involving the genu and splenium in patients with AIS with a dominant right convex scoliotic curve. These observations might not be just a casual phenomenon but could have implications related to underlying spinal asymmetry. The pseudo-right lateralization of the CC might be part of the known generalized asymmetry of many functions and structures proposed in AIS, such as cerebral hemisphere asymmetries,^{7,9,11} vestibular apparatus asymmetries,¹² extraspinal left-right skeletal length asymmetries, and proximodistal lower limb disproportions (allometry),³⁵ though the exact mechanism and clinical significance (whether it is related to primary etiopathogenesis or is a secondary consequence of AIS) is not certain.

One of the limitations of this study is the unequal number of subjects in the mild, moderate, and severe groups of AIS, with most subjects belonging to moderate group. This is the genuine distribution of AIS in the daily clinical setting and probably explains why a significant difference is consistently observed in the moderate group only, while the other subgroups, though showing similar trends, have not reached the significance level. For future studies, a concerted effort of multiple centers with recruitment of more patients with mild and severe AIS would be useful to further investigate the relationship between those alterations in the CC and the effect on scoliosis curve severity.

The neuropsychologic dysfunctions of AIS are usually subclinical, though they can be elicited by specific tests; however, these tests are sophisticated and expensive and have not been included in this study, which is another limitation. Examples of these specific tests, however, have been well-documented in the published literature, which include video-oculography for visuo-oculomotor dysfunction³ and electromyographic analysis for gait³⁶ in AIS.

Although there is a significant FA difference in the CC and related cerebral regions, reflecting white matter microstructural changes, the FA values derived from DTI do not involve non-Gaussian properties of biologic tissues and intravoxel fiber crossings,³⁷ which may interfere with FA value accuracy. Diffusional kurtosis imaging, which involves more sophisticated calculations, can overcome the limitations by eliminating some confounding factors. Future studies using the more advanced diffusional kurtosis imaging might be useful to further validate our DTI findings.

CONCLUSIONS

Reduced FA was found in the genu and splenium in patients with AIS compared with matched controls on both 2D and 3D seg-

mentation analysis. There was corresponding reduction of FA in fibers interconnecting the primary somatosensory cortex and visual cortex, passing through the splenium in patients with AIS. Furthermore, relatively reduced FA was also observed on the left side of the above regions of the CC in patients with AIS presenting with a typical right scoliotic curve. The above microstructural changes of the white matter fiber tracts might be related to the documented somatosensory function impairment and visuo-oculomotor dysfunction in AIS.
