Application of 3D Fast Spin-Echo T1 Black-Blood Imaging in the Diagnosis and Prognostic Prediction of Patients with Leptomeningeal Carcinomatosis

ABSTRACT

BACKGROUND AND PURPOSE: Contrast-enhanced 3D fast spin-echo T1 black-blood imaging selectively suppresses the signal of blood flow and could provide a higher contrast-to-noise ratio compared with contrast-enhanced 3D ultrafast gradient recalled echo (contrast-enhanced gradient recalled echo) and 2D spin-echo T1WI (contrast-enhanced spin-echo). The purpose of our study was to evaluate whether black-blood imaging can improve the diagnostic accuracy for leptomeningeal carcinomatosis compared with contrast-enhanced gradient recalled-echo and contrast-enhanced spin-echo and, furthermore, to determine whether the grade of leptomeningeal carcinomatosis evaluated on black-blood imaging is a significant predictor of progression-free survival.

MATERIALS AND METHODS: Leptomeningeal carcinomatosis (n = 78) and healthy (n = 3) groups were enrolled. Contrast-enhanced gradient recalled-echo, contrast-enhanced spin-echo, and black-blood imaging were separately reviewed, and a diagnostic rating (positive, indeterminate, or negative) and grading of leptomeningeal carcinomatosis were assigned. The diagnostic accuracies of the 3 imaging sequences were compared in terms of leptomeningeal carcinomatosis detection. The Kaplan-Meier and the Cox proportional hazards model analyses were performed to determine the relationship between the leptomeningeal carcinomatosis grade evaluated on black-blood imaging and progression-free survival.

RESULTS: Black-blood imaging showed a significantly higher sensitivity (97.43%) than contrast-enhanced gradient recalled-echo (64.1%) and contrast-enhanced spin-echo (66.67%) (P < .05). In terms of specificities, we did not find any significant differences among contrast-enhanced gradient recalled-echo (90.32%), contrast-enhanced spin-echo (90.32%), and black-blood imaging (96.77%) (P > .05). A Cox proportional hazards model identified the time to metastasis, Karnofsky Performance Scale status, and a combination of the leptomeningeal carcinomatosis grade with a linear pattern as independent predictors of progression-free survival (P < .05).

CONCLUSIONS: Black-blood imaging can improve the diagnostic accuracy and predict progression-free survival in patients with leptomeningeal carcinomatosis.

ABBREVIATIONS: CE = contrast-enhanced; GRE = gradient recalled-echo; ICC = intraclass correlation coefficient; KPS = Karnofsky Performance Scale; LC = leptomeningeal carcinomatosis; PFS = progression-free survival; SE = spin-echo

Leptomeningeal carcinomatosis (LC) is a devastating complication of systemic cancer that occurs in approximately 5%–10% of patients with solid tumors and is most commonly observed in patients with breast cancer, lung cancer, or melanoma.1 Recently, the incidence of LC has gradually started increasing as the diagnostic rate of primary cancer has increased and the outcome of primary cancer has improved due to effective antineoplastic treatments.2,3 However, the prognosis for patients with LC is extremely poor, and the median survival rate is 4–6 weeks if not treated, which can be increased to 4–6 months after active treatment with chemotherapy or radiation therapy.4,5 In addition,
proper treatment can prevent the deterioration of neurologic symptoms that impair the patient’s quality of life.\textsuperscript{1,6} Therefore, early diagnosis and proper treatment of LC are the most important strategies to improve the overall survival and quality of life of patients with LC.

However, the diagnosis of LC is still a challenge. Identification of malignant cells by CSF cytology has been the diagnostic criterion standard, but the sensitivity of CSF cytology is limited. The initial cytology is falsely negative in up to 40%–50% of patients with pathologically proved LC, and this measure demonstrates a sensitivity of approximately 75% on repeat spinal tapping.\textsuperscript{7,8} With improved visualization of the subarachnoid space, MR imaging, especially contrast-enhanced (CE) T1-weighted imaging, is regarded as a reliable technique for confirming this diagnosis and for assessing the extent of the lesion and its response to therapy.\textsuperscript{9,10} However, LC is often missed on MR imaging because the leptomeninges is an anatomically thin membrane and subtle contrast enhancement is often mistaken for blood vessels by readers.

A recently introduced 3D fast spin-echo T1 black-blood imaging is one of the 3D spin-echo sequences that nullifies signals from moving flows\textsuperscript{11,12}; in other words, it selectively suppresses the signal of blood flow and provides a higher contrast-to-noise ratio. Several studies have demonstrated that black-blood imaging can improve the diagnostic accuracy of small brain parenchymal metastases due to its higher contrast-to-noise ratio.\textsuperscript{13,14} However, there are few studies that have explored the value of black-blood imaging in the detection of LC, and we hypothesized that black-blood imaging has a better diagnostic accuracy in detecting LC than CE 3D ultrafast gradient recalled-echo (CE GRE) and 2D spin-echo T1WI (CE SE).

Therefore, the purpose of our study was to evaluate whether black-blood imaging can improve the diagnostic accuracy for LC proved pathologically or clinically by comparing it with CE GRE and CE SE and, furthermore, to determine whether the grade of LC evaluated on black-blood imaging is a significant predictor of the patient’s performance status and progression-free survival (PFS).

**MATERIALS AND METHODS**

**Patients**

This retrospective study was approved by the Seoul National University Hospital Institutional Review Board (SNUH IRB) with a waiver of informed consent. From January 2014 to October 2016, MR imaging was performed in 1758 consecutive patients (older than 18 years of age), including black-blood imaging, CE GRE, and CE SE. Among them, 78 patients met the following inclusion criteria: 1) having been diagnosed with LC and meeting the criteria below; 2) having contrast MR images of the brain, including black-blood imaging, CE GRE, and CE SE; and 3) having at least a 3-month follow-up if no progression. The exclusion criteria were as follows: 1) patients with prior intrathecal chemotherapy or whole-brain radiation therapy; and 2) patients with imaging studies from outside institutions or inadequate MR images for the analysis because of motion artifacts. The mean age of the patients was 56.5 years (age range, 19–87 years; 48 female and 30 male patients). The diagnoses were lung cancer ($n = 51$ patients), breast cancer ($n = 19$ patients), gastric cancer ($n = 5$ patients), gallbladder cancer ($n = 1$ patient), cholangiocarcinoma ($n = 1$ patient), and osteosarcoma ($n = 1$ patient).

In addition, 31 patients without LC were also enrolled. We considered LC to be absent if there was no clinical evidence of LC with a follow-up of $\geq 12$ months, in addition, negative cytology if CSF cytology was performed.\textsuperscript{15} The clinical criteria called for no new or progressive neurologic deficits for $\geq 12$ months after the MR imaging. Only the negative CSF cytology criterion is not adequate because even three separate lumbar punctures can have a false negative rate of $\geq 10\%$.\textsuperscript{7,8}

**Diagnosis of LC**

The diagnosis was made in 1 of 2 ways: (1) a CSF cytology positive for malignant cells, which was repeated up to three times or (2) MRI scans showing LC on both initial and 2–3 month follow-up studies in patients with suspicious cytology (atypical cells) or biochemical test (elevated protein level and/or decreased glucose level in CSF).\textsuperscript{1,7,8,10,16–19} The various MR imaging findings used for the diagnosis included superficial sulcal/cisternal enhancement, sulcal/cisternal obliteration, multiple tiny superficial nodules along the sulci/cistern, enhancement of cranial nerves, and hydrocephalus.\textsuperscript{7,10} LC may grow in a linear pattern, creating a thin layer of cells spread diffusely over the brain surfaces, or in a nodular growth pattern, involving the leptomeninges in a multifocal skip pattern with intervening tumor-free areas.\textsuperscript{4,20}

**MR Imaging Acquisition**

In this study, MR imaging examinations were performed on 1 of three 3T MR imaging systems with 32-channel head coils, which included Verio (Siemens, Erlangen, Germany), Achieva dStream (Philips Healthcare, Best, the Netherlands), and Discovery MR750w (GE Healthcare, Milwaukee, Wisconsin) scanners. Each MR imaging scanning session included CE GRE, CE SE, and black-blood imaging, sequentially. CE T1WI was obtained after the intravenous administration (manual injection) of gadobutrol.
(Gadovist; Bayer Schering Pharma, Berlin, Germany) at a dose of 0.1 mmol/kg of body weight.

The study was conducted in 63, 27, and 19 of 109 patients using the Verio, Achieva dStream, and Discovery MR750w scanners, respectively. The parameters used in the MR imaging examinations are summarized in On-line Table 1.

**Image Analysis**

A senior neuroradiologist (17 years of brain MR imaging experience) who was blinded to clinical information reviewed the images from each sequence individually and separately and assigned a diagnostic rating (positive, indeterminate, or negative) and a grading of LC. We also scored leptomeningeal enhancement on MR imaging on a 0–5 scale. For each of the cerebral hemispheres, the presence of leptomeningeal enhancement was scored as 0 (absent), 1 (in 1 lobe), or 2 (>1 lobe). For the infratentorial area, it was scored as 0 (absent) or 1 (present). In addition, other imaging parameters were also collected, including the presence and number of brain metastases, the presence of hydrocephalus, the pattern of LC (linear or nodular), and the location of LC in the brain.

For the analysis of the interobserver agreement, 4 neuroradiologists (with 6, 8, 9, and 17 years of neuroimaging experience) who were blinded to clinical information analyzed 109 sets of MR images from each sequence individually and separately and assigned a diagnostic rating (positive, indeterminate, or negative) to each location of the cerebral hemispheres and a grading of LC.

**Clinical Variables and Follow-Up**

The patients’ medical records were reviewed, and demographic and clinical data were collected, including age, sex, date of initial cancer diagnosis, date of LC diagnosis, Karnofsky Performance Scale (KPS) score at LC diagnosis, primary cancer histology, history of intrathecal chemotherapy or radiation to the brain, initial staging, and treatment with hormone therapy, chemotherapy, and radiotherapy.

**FIG 1.** MR images of a 60-year-old female patient with lung cancer. On all contrast-enhanced 3D ultrafast GRE (A and D), SE TIWI (B and E), and black-blood imaging (C and F), leptomeningeal enhancement along the sulci of the bilateral cerebral hemispheres and cerebellar surface was observed (arrows).
and subsequent treatment, and the date of last follow-up. The demographic and clinical information is summarized in Table 1.

For all enrolled patients with LC, treatment was performed properly as decided by an oncology team, and tumor progression was tracked at an outpatient clinic with follow-up MR imaging until death or March 2017 if the patient was still alive. Among the 78 patients with LC, 38 patients with lung cancer who underwent at least 1 follow-up MR imaging and had follow-up for at least 3 months if no progression were analyzed with the Kaplan-Meier and the Cox proportional hazards models. Tumor progression was designated as the time when the grade of LC evaluated on the MR imaging was elevated or when the size or number of the primary cancer or metastatic lesions increased. Progression-free survival was defined as the time span from the date of the brain MR imaging to the date of the documented progression or the last clinical follow-up.

Statistical Analysis
The data were checked with the Shapiro-Wilk test for normality and the Levene test for equality of variance. The sensitivity and specificity of the different MR images were calculated, and the Fisher exact test was performed. Additionally, the KPS scores were compared between the groups with different grades using a Mann-Whitney U test. To perform the Kaplan-Meier analysis, we dichotomized each parameter regarding the cut-point, which was determined using the method of Contal and O’Quigley, which is based on the log-rank test statistic. For the 38 patients mentioned above, the Kaplan-Meier and the Cox proportional hazards model analyses were performed to determine the relationship between the LC grade evaluated on black-blood imaging and PFS. Additionally, the intraclass correlation coefficient (ICC) was used to assess interobserver agreement. A P value < .05 was considered a significant difference. All statistical analyses were performed using commercially dedicated software (MedCalc for Windows, Version 17.6, MedCalc Software, Mariakerke, Belgium; and SPSS 23 software for Windows, IBM, Armonk, New York).

RESULTS
Diagnostic Accuracy of the MR Images
Black-blood imaging (76 of 78 patients with LC, 97.43%) showed a significantly higher sensitivity than CE GRE (50 of 78, 64.1%) and CE SE (52 of 78, 66.67%) for the detection of LC (P < 0.001) (Table 2 and Figs 1 and 2). In terms of specificities, we did not find a significant difference among CE GRE (28 of 31 healthy patients,
Table 4: Kaplan-Meier analysis of the imaging and clinical parameters of PFS (Table 3). In addition, the Verio, Achieva dStream, and Discovery MR750w scanners did not show significantly different sensitivities or specificities for CE SE, CE GRE, or black-blood imaging (P > .05) (On-line Tables 2 and 3).

**LC Grade and KPS**

Among 78 patients with LC, only 3 patients (3.9%) had no clinical symptoms at diagnosis. The other 75 patients had neurologic symptoms at the time of diagnosis, and 38 patients (48.7%) had symptoms or signs referable to 1 compartment of the CNS (brain, cranial nerve, or spinal cord), whereas 37 patients (47.4%) had symptoms or signs referable to multiple levels of the neuraxis. Headache, altered mentality, nausea/vomiting, gait difficulty, leg weakness, diplopia, and facial palsy were the most common findings. There was no significant correlation between the presence of each symptom and the LC grade (P > .05). In addition, the patients with an LC grade of 5 based on the black-blood imaging had significantly lower KPS scores than the patients with LC grades of 0–4 (P < .001) (On-line Table 4).

**Relationship between LC and PFS**

For the 38 patients with lung cancer, the mean follow-up was 4.64 ± 4.48 months. Among them, 26 (68.4%) patients showed disease progression during the follow-up period. The LC grade evaluated on the follow-up MR imaging was elevated in 7 of the 26 patients (26.9%), the size or number of the primary cancer increased in 4 of the 26 patients (30.8%), and the size or number of the metastatic lesions increased in 11 of the 26 patients (42.3%). The median PFS of the patients was 4.17 months (95% CI, 3.10–6.17 months). The estimated 1-year PFS rate was 26.1%.

**DISCUSSION**

Our study demonstrates that black-blood imaging could improve the diagnostic accuracy for LC, especially for sensitivity, compared with CE GRE and CE SE and that it also has higher interobserver agreement. The grade of LC evaluated on the black-blood imaging showed significant associations with KPS scores. In addition, multivariate analysis using a Cox proportional hazards model revealed that the grade of LC evaluated on black-blood imaging is a significant predictor of PFS when combined with the LC enhancement pattern. On the basis of our study results, we believe that black-blood imaging could complement the low sensitivity of CSF cytology and provide a significant marker of PFS in patients with LC.

To date, several studies have compared the diagnostic accuracy of different MR images in detecting LC. Until now, the sensitivity of MR imaging to LC has been variably known from 20% to 71%, Singh et al showed the sensitivity of 2D-FLAIR and CE T1-weighted SE in patients with cytologically confirmed LC, and the result was 34% in FLAIR and 66% in CE T1-weighted SE. A subsequent study by Singh et al showed that the sensitivity time, 11.63 versus 3.37 months; P = .036), and a combination of the LC grade and pattern (median PFS time, 4.87 versus 1.77 months; P = .009) as significant markers of PFS (Fig 3). Additionally, a Cox proportional hazards model identified a shorter time to metastasis (hazard ratio, 0.25; 95% confidence interval, 0.09–0.71; P = .009), a lower KPS (hazard ratio, 0.33; 95% CI, 0.12–0.89; P = .029), and a combined LC grade with a linear pattern (hazard ratio, 2.77; 95% CI, 1.08–7.08; P = .034) as separate independent predictors of PFS (On-line Table 5).
and specificity of CE FLAIR for detecting LC were 41% and 88%, while those of CE T1-weighted MR imaging were 59% and 93%, respectively. LC diagnosis using contrast-enhanced MR imaging has relatively high specificity but still has low sensitivity.

A recently introduced black-blood imaging sequence is one of the 3D SE sequences that nullifies signals from moving flows, in other words, the signal of blood flow. Several studies have demonstrated that black-blood imaging can improve the diagnostic accuracy of small brain parenchymal metastasis due to its higher contrast-to-noise ratio, compared with CE 3D ultrafast GRE and SE T1WI. This finding has theoretically been supported by several studies that demonstrated that lesions in CE 3D ultrafast GRE sequences are less enhanced by gadolinium than in SE-based sequences. In addition, a recent study comparing 2D-FLAIR, 2D-CE T1-weighted GRE, and black-blood imaging in the diagnosis of LC demonstrated that black-blood imaging showed a better detection rate of LC, regardless of the degree of the rater’s experience.

Our study results were in good agreement with previous clinical studies, but our study differs from the previously published studies in some respects. First, we used clear inclusion criteria for those with LC and healthy patients. We only included pathologically or clinically proved patients with LC with a sufficient follow-up period. In addition, we considered LC absent if there was no clinical evidence of LC for a sufficient follow-up after MR imaging (>12 months). Second, we evaluated not only the diagnostic accuracy but also whether the grade of LC evaluated on black-blood imaging was a significant predictor of the patient’s KPS scores and PFS. In our study, multivariate analysis showed that the grade of LC evaluated on black-blood imaging was a significant predictor of PFS when combined with the LC enhancement pattern. Therefore, the use of combination of the LC grade and pattern as prognostic biomarkers could improve the stratification of patients with LC at risk of progression and may allow modification of surveillance strategies for specific subgroups who are at high risk of progression. Early diagnosis and proper treatment of progression are the most important strategies for improving overall survival and preventing the deterioration of neurologic symptoms that impair the patient’s quality of life. Third, we conducted an analysis of the interobserver agreement, and black-blood imaging was revealed to have a slightly higher ICC than the other sequences for all locations of the cerebral hemispheres, including the cranial nerves. Fourth, our results revealed that there was no significant difference in the diagnostic accuracy of black-blood imaging among the Verio, Achieva dStream, and Discovery MR750w scanners.

There were, however, several limitations in this study. First, this was a retrospective, single-center-based study with some potential bias. In addition, the sample size was rather small because we included only the patients with pathologically confirmed LC or definitive MR imaging findings of LC. Therefore, further studies with a larger number of cases should be performed. Second, unlike previously published studies, the MR imaging examinations were performed with different 3T MR imaging system vendors in this study (Siemens, GE Healthcare, and Philips Healthcare), and this feature may have influenced the overall study results. However, the sensitivity and specificity of each sequence showed no significant differences among the different vendors. Third, in this study, not all conditions of patients were pathologically confirmed. However, we included only patients with a definite sufficient follow-up period in this study. Fourth, our study did not include a postcontrast FLAIR sequence, which is also known to be sensitive to LC. Our hospital obtained black-blood imaging to better detect small metastases or LC in patients with...
Cancer but did not routinely obtain a postcontrast FLAIR image due to the limitation of scan time. Therefore, further study for the comparison with postcontrast FLAIR is warranted. Finally, in our study, each MR imaging scanning session included CE GRE, CE SE, and black-blood imaging, sequentially. Several studies have suggested that not only on the postcontrast scans performed at an early stage after administration of contrast medium but also on later images, contrast still is sufficient to obtain images of the tumor.27,28 In addition, a previous study suggested that imaging time delay did not have an effect on lesion conspicuity.29 However, the scan time after contrast administration may cause some timing bias, so further study that randomizes the order of postcontrast sequences is warranted.

CONCLUSIONS

Black-blood imaging could improve the diagnostic accuracy for LC, especially in sensitivity, compared with CE GRE and CE SE, and it also has a higher interobserver agreement. In addition, a combination of the LC grade and pattern could be an independent predictor of PFS in patients with LC. Therefore, we believe that black-blood imaging is a clinically useful sequence that can play an important role in the early diagnosis as well as the prognosis prediction of patients with LC.
