Morphometric MRI Analysis: Improved Detection of Focal Cortical Dysplasia Using the MP2RAGE Sequence

ABSTRACT

BACKGROUND AND PURPOSE: Focal cortical dysplasias are the most common resected epileptogenic lesions in children and the third most common lesion in adults, but they are often subtle and frequently overlooked on MR imaging. The purpose of this study was to evaluate whether MP2RAGE-based morphometric MR imaging analysis is superior to MPRAGE-based analysis in the detection of focal cortical dysplasia.

MATERIALS AND METHODS: MPRAGE and MP2RAGE datasets were acquired in a consecutive series of 640 patients with epilepsy. Datasets were postprocessed using the Morphometric Analysis Program to generate morphometric z score maps such as junction, extension, and thickness images based on both MPRAGE and MP2RAGE images. Focal cortical dysplasia lesions were manually segmented in the junction images, and volumes and mean z scores of the lesions were measured.

RESULTS: Of 21 focal cortical dysplasias discovered, all were clearly visible on MP2RAGE junction images, whereas 2 were not visible on MPRAGE junction images. In all except 4 patients, the volume of the focal cortical dysplasia was larger and mean z scores were higher on MP2RAGE junction images compared with the MPRAGE-based images (P = .005, P = .013).

CONCLUSIONS: In this study, MP2RAGE-based morphometric analysis created clearer output maps with larger lesion volumes and higher z scores than the MPRAGE-based analysis. This new approach may improve the detection of subtle, otherwise overlooked focal cortical dysplasia.

ABBREVIATIONS: FCD = focal cortical dyplasia; MAP = Morphometric Analysis Program

Focal cortical dysplasias (FCDs) are the most common epileptogenic lesions in children undergoing epilepsy surgery and the third most common cause in adults.1 They encompass a broad spectrum of histopathologic abnormalities and have recently been classified in a 3-tiered system, in which FCD type I has abnormal radial and/or tangential laminations and FCD type II is composed of dysmorphic neurons either without (FCD IIa) or with (FCD IIb) balloon cells. FCD type III lesions are dysplastic lesions occurring alongside other lesions, eg, hippocampal sclerosis or tumors.3 Whether a dysplastic lesion is detected on MR imaging depends on the degree of histopathologic abnormality and on the quality of the MR imaging examination.5 The impact of the MR imaging quality can be derived from the increasing proportions of FCD type II in cohorts of patients undergoing epilepsy surgery.4 Many of these FCDs were detected following postprocessing of an MPRAGE sequence, which highlighted subtle and thus equivocal findings on conventional, mostly FLAIR, sequences.5,6 For MR imaging post-processing, several epilepsy centers use the Morphometric Analysis Program (MAP), which is based on algorithms of the freely available Statistical Parametric Mapping (SPM; http://www.fil.ion.ucl.ac.uk/spm/software/spm12) software. By comparison with a normal data base, 3 different morphometric maps are generated that highlight suspicious brain regions characterized by subtle blurring of the gray-white junction, abnormal cortical gyration, or abnormal cortical thickness.7,8 The MP2RAGE sequence is a refinement of the MPRAGE sequence. It combines 2 MPRAGE datasets acquired, interleaved at different TIs, and creates a homogeneous T1-weighted contrast

with an intrinsic correction of $B_1$ inhomogeneities and reduced residual proton density and $T2^*$ weighting. $T1$ relaxation times can be derived from the MP2RAGE contrast, which has been shown to be highly reproducible both across subjects and within the same subject using different scanning parameters.9 We conducted this prospective study because we hypothesized that due to higher $B_1$ homogeneity, the MP2RAGE sequence is better suited for morphometric MR imaging analysis and the resulting FCD detection than the traditionally used MPRAGE sequence.

**Materials and Methods**

Within a 4-year period (July 1, 2015–June 30, 2019), 640 patients with epilepsy were studied with an epilepsy-dedicated protocol10 and an additional MP2RAGE sequence on a 3T scanner (Magnetom Prisma; Siemens) (Table). The study was in accordance with the 1964 Helsinki Declaration and its later amendments and was approved by the local ethics committee (University Medical Center Freiburg).

**Morphometric MR Imaging Analysis**

Morphometric MR imaging analysis was performed on MPRAGE and MP2RAGE images using a fully automated script, MAP, running in Matlab, Version R2014b (MathWorks). The current version of the program (MAP18) corresponds to previous implementations known as MAP076,11,12 but now uses algorithms of SPM12, eg, the algorithm for normalization into Montreal Neurological Institute space known as “unified segmentation” (with small modifications in SPM12 compared with SPM5; see SPM12 Manual, page 51f, www.fil.ion.ucl.ac.uk) and the recently improved segmentation into 5 tissue classes instead of 3 as in SPM5. The creation of the morphometric maps has been described in detail in previous publications.7,8,13,14 Briefly, each $T1$ input image is normalized to Montreal Neurological Institute space, simultaneously corrected for intensity inhomogeneities and segmented in different tissue compartments. The distribution of gray and white matter is analyzed on a voxelwise basis and compared with a normal data base. On the basis of this analysis, 3D morphometric maps, called extension image, junction image, and thickness image, are generated. These are $z$ score maps in which brain regions that deviate from the normal data base have
higher z scores and appear bright, thereby highlighting typical
MR imaging features of FCDs, such as abnormal gyration and
abnormal extension of gray matter into white matter (extension image), blurring of the gray-white matter junction (junction image), and abnormal cortical thickness (thickness image).

Because the junction image is the most sensitive of these
maps, it was the focus of this study, and its creation will be
described in more detail here:

Means and SDs of the voxel intensities in the gray and white
matter compartments are used to determine individual lower (mean
gray matter signal intensity + one-half gray matter SD) and upper
(mean white matter signal intensity – one-half white matter SD) in-
tensity thresholds for filtering and conversion of the normalized and
intensity-corrected input image to a binary image. Each voxel with a
gray value between these thresholds is set to 1 in the resulting binary
image, and the other voxels are set to zero. The resulting binary
image is then smoothed by a 3D convolution filter and compared
with a normal data base. The datasets forming the normal database
have been processed in the same way as described above and then
used to create an average image and an image providing SDs for all
voxel positions. These are used to transform the smoothed binary
image into the final junction image with z score normalized data.

Bright regions in the junction image correspond to cortical areas
with a less defined border between gray and white matter and a
broader transition zone compared with the normal data base.8

For the present study, 2 different normal data bases of healthy
controls have been used, one for MPRAGE data and the other for
MP2RAGE data. They consist of MPRAGE and MP2RAGE
datasets, respectively, of the same
cohort of 154 persons (88 women, 66
men) with a mean age of 33.9 years
(range, 20–64 years), measured on a 3T
Magnetom Prisma scanner.

**Evaluation**

All morphometric maps (ie, junction,
extension, and thickness images) were
displayed in MRicro (https://people.
cas.sc.edu/rorden/mricro/mricro.html)
in the full-range contrast setting and
screened alongside coregistered 3D-
FLAIR sequences for dysplastic lesions.
An FCD was diagnosed when the typi-
cal radiologic criteria were clearly iden-
tifiable on either T1 or FLAIR images.
In such cases, lesions were manually
segmented on axial slices of the junc-
tion images generated from MPRAGE
and MP2RAGE sequences, respectively,
according to the extent of the bright
area highlighting the blurring of the
gray-white matter junction. All segmen-
tation results were stored as ROIs, and
volumes and z scores were measured.

Thickness and extension images
were evaluated only for positive or neg-
ative findings in a consensus reading by 2 readers with >3 and
>20 years’ experience in clinical neuroimaging. In this context,
MPRAGE and MP2RAGE junction images were also examined for
false-positive lesions, ie, findings without correlation in the FLAIR
sequences.

**Statistics**

The Wilcoxon signed rank test was used to compare the volumes
and z scores of the FCDs obtained with MPRAGE- versus
MP2RAGE-based junction images. Statistical analysis and graphic
representation were performed with SPSS 22 (IBM) and R (https://

**RESULTS**

Twenty-one lesions with MR imaging characteristics of FCD type II
were identified in 20 patients (mean age, 27 ± 14.9 years; range, 7–
60 years). An operation has been performed in only 7 patients so far
(2 with FCD IIa, 4 with FCD IIb, and in 1 patient [patient 9] in
whom only ectopic neurons were found). Seizure outcome has been
available in 6 patients so far and was Engel Epilepsy Surgery
Outcome Scale IA in 4 patients and IVB in 2 patients (patients 1
and 17; On-line Table).

Postprocessing of the MPRAGE and MP2RAGE sequences
helped to detect 2 FCD IIa lesions, which were overlooked on con-
ventional MR images (patients 1, 2; Fig 1). Two lesions (patients 14,
18; Fig 2) were invisible on MPRAGE-based junction images but
clearly identified on MP2RAGE-based images. In 20 patients, we
detected, in total, 34 (MPRAGE junction) and 32 (MP2RAGE junc-
tion) false-positive lesions, respectively (for individual values, see

[FIG 2. FCD with the transmantle sign of the right precentral gyrus in a 7-year-old girl with seiz-
ures (patient 18). Despite movement artifacts, the lesion is clearly visible on FLAIR (A and D) and
MP2RAGE-based junction images (F). In an MPRAGE-based junction image (C) for comparison, the
lesion is not clearly distinguishable. Strong T1WI contrast is seen in a uniform MP2RAGE image (E)
compared with MPRAGE (B).]
On-line Table). Distribution of false-positive findings was similar between both techniques, with no false-positives in 3 MPRAGE/6 MP2RAGE datasets, 1 false-positive in 7/6, two false-positives in 7/2, three in 1/4, four in 2/1, and 5 false-positive findings in 1 MP2RAGE dataset.

The median volumes of true-positive lesions, manually segmented on junction images, were 0.586 mL (range, 0.114–7.946 mL; standard error of the mean, 0.403 mL) for the MPRAGE-based junction images and 0.829 mL (range, 0.182–8.690 mL; standard error of the mean, 0.441 mL) for the MP2RAGE-based junction images, respectively ($P = .005$). The median $z$ scores on full-range contrast junction images were 4.452 (range, 2.111–9.125; standard error of the mean, 0.381) for MPRAGE and 5.643 (range, 1.762–13.176; standard error of the mean, 0.654) for the MP2RAGE-based analysis, respectively ($P = .013$). The distribution of volumes and $z$ scores, including median values, are presented in Fig 3.

A comparative analysis showed that MAP-junction was the most sensitive morphometric map (Figs 2, 4, and 5). Evidence of disturbed GM-WM differentiation was found in the MP2RAGE-based junction images of all 21 FCDs in 20 patients (On-line Table and Figs 1, 2, 4, and 5). In contrast, abnormalities in the thickness and extension images were only present in 13/21 and 16/21 lesions for the MPRAGE- and 13/21 and 18/21 lesions for the MP2RAGE-based analysis.

**DISCUSSION**

In the present study, postprocessing of an MP2RAGE sequence yielded larger lesion volumes and lesion $z$ scores of the junction images compared with the MPRAGE sequence. In addition, it helped to detect 2 FCDs that were not highlighted on MPRAGE-based junction images.

The junction images display the abnormal transition of the gray-white matter junction. Blurring of the gray-white matter transition is a common feature in type I and II FCDs. The prevalence of transition zone abnormalities on structural (nonpostprocessed) MR imaging ranges between 53% (FCD Ia) and 79% (FCD IIb).15 The sensitivity and specificity of MAP junction maps in histology-proved FCDs, based on T1WI, have been reported as 64% and 96%.16 Displaying larger and brighter lesions, the MP2RAGE sequence likely increases the sensitivity and diagnostic confidence, which may have an impact on the decision to proceed with invasive electroencephalography recordings or epilepsy surgery.

The abnormal cortical morphology as reflected by an increased cortical thickness and abnormal extension of gray matter into white matter is common in FCD II but is typically absent in FCD I and III. However, abnormal cortical morphology is more difficult to identify on the extension and thickness images than the abnormal transition of the gray-white matter junction on the corresponding junction images. In most cases, the lesions were detected with the aid of the junction images. However, there was a tendency for better detection of FCDs on MP2RAGE-based extension images (positive findings in 18/21 versus 16/21 lesions), whereas
thickness images only had positive findings in 13/21 lesions in both techniques. Our finding of larger lesion sizes in MP2RAGE-based MAP analysis raises the question about the real size of a lesion. By demonstrating larger lesion volumes, MP2RAGE-based junction maps may be superior in defining peripheral lesion components. Furthermore, positive findings on extension and thickness images suggest that an integrated definition and lesion detection in an automated approach represent the next step in MAP-based FCD postprocessing. Even if the resection of the subcortical component does not seem to improve the outcome, an integrative definition of the lesion component at the cortico-medullary junction should be sought.

Recently, a modification of the MP2RAGE sequence with altered TIs to null CSF and white matter in the 2 respectively acquired TI images has been published. The fluid and white matter suppression sequence appears ideally suited to search for FCD, but its use for morphometric analysis again requires the buildup of a sequence-specific normal data base of healthy controls.

A limitation of this study is the difficulty of evaluating whether in light of a higher sensitivity of MP2RAGE-based junction images, there are also more false-positive findings. In this study, we performed a qualitative visual evaluation with the aid of the results of the morphometric analysis. We did not use a specific threshold value for an automated detection of FCD, but re-assessed the “bright spots” on the morphometric analyses on FLAIR sequences to discover subtle lesions with abnormalities at the gray-white matter interface. Therefore, a further quantification and assessment of false-positive findings in patients or healthy controls is simply not possible. To at least estimate false-positive findings in patients, we visually compared MPRAGE- and MP2RAGE-based junction images using the full-range contrast setting of MRIcro. We found 34 and 32 false-positives in 20 patients on MPRAGE- and MP2RAGE-based images, respectively, with a similar distribution between both techniques. No differences with regard to the cluster size or the z scores of false-positives were found.

To estimate false-positive findings in healthy controls, we analyzed 70 healthy controls, assuming that they did not have FCD. With a general linear model and a leave-one-out strategy, each voxel was compared with the corresponding voxel of the remainder. Number and z scores of false-positive voxels (P < .001, P < .05 family-wise error-corrected) were not different between MPRAGE and MP2RAGE datasets (unpublished data).

However, at this point, for the detection of FCD in an epileptologic setting, sensitivity is more important than specificity or the number of false-positive findings because an undetected or overlooked lesion may prevent the patient from accessing an epilepsy surgery program. Conversely, no putative FCD would undergo an operation directly, but first the epileptogenic potential of a possible lesion would always have to be verified using electrophysiologic methods. Therefore, a high sensitivity is more crucial for this type of clinical situation than a high specificity.

Another limitation is the relatively low number of FCDs and the fact that histopathologic proof has been obtained in only 7 patients so far. In 1 patient (patient 9), only ectopic neurons but no FCD were encountered. However, because the patient was seizure-free 3 months after the operation, a neuropathologic sampling error should also be taken into consideration.

Recently, a modification of the MP2RAGE sequence with inversion pulses to suppress CSF and white matter has been published. The fluid and white matter suppression sequence appears ideally suited to search for FCD but again requires the buildup of a data base of healthy controls and a larger number of patients with FCD.

**CONCLUSIONS**

MP2RAGE compared with MPRAGE produced junction images with larger FCD lesion volumes and higher lesion z scores, which may improve the detection of FCD in patients with focal epilepsy.

FIG 5. FCD with a transmantle sign of the right superior frontal gyrus (bottom-of-sulcus dysplasia) (FLAIR A and D) in an 11-year-old girl with left upper and lower limb somatosensoric aura and motor seizures (patient 20). The MPRAGE- (B and C) and MP2RAGE-based junction images (E and F) match the signal abnormalities at the gray matter junction as a characteristic feature of FCD type II. MP2RAGE delivers, in this case, higher contrast junction images and better lesion definition compared with MPRAGE.
