Safety and Efficacy of the Woven EndoBridge Device for Treatment of Ruptured Intracranial Aneurysms: A Systematic Review and Meta-analysis

M.A. Essibayi, G. Lanzino, and W. Brinjikji

ABSTRACT

BACKGROUND: The Woven EndoBridge device has been increasingly used to treat wide-neck aneurysms, particularly ruptured ones.

PURPOSE: Our aim was to investigate the safety and efficacy of the Woven EndoBridge device in the treatment of ruptured intracranial aneurysms.

DATA SOURCES: All studies evaluating the outcomes of Woven EndoBridge device use in the treatment of ruptured intracranial aneurysms from inception through 2020 were searched on Ovid Evidence-Based Medicine Reviews, EMBASE, MEDLINE, Scopus, and the Web of Science Core Collection.

STUDY SELECTION: Eighteen studies encompassing 487 patients with 496 ruptured aneurysms treated with the Woven EndoBridge device were included.

DATA ANALYSIS: We studied rates of rerupture and retreatment, angiographic outcomes at the last follow-up point, complications, and mortality rates. Data were collected on anticoagulation and antiplatelet use. Meta-analysis was performed using the random effects model.

DATA SYNTHESIS: The rate of late rebleeding was 1.1% (95% CI, 0.1%–2.1%). The treatment-related perioperative complication rate and the overall clinical complication rate were 13.2% (95% CI, 9.2%–17.2%) and 3.2% (95% CI, 1.6%–4.7%), respectively. Thirteen hemorrhagic (2%; 95% CI, 0.8%–3.3%) and 41 thromboembolic (6.8%; 95% CI, 4.6%–9%) complications occurred. Favorable clinical outcomes were achieved in 85% of patients. Procedure-related mortality and overall mortality rates were 2.1% (95% CI, 0.8%–3.3%) and 11.5% (95% CI, 7%–16%), respectively. At last follow-up, an adequate occlusion rate was 87.3% (95% CI, 82.1%–92.4%) and the retreatment rate was 5.1% (95% CI, 3%–7.3%).

LIMITATIONS: Our meta-analysis is limited by selection bias and high heterogeneity.

CONCLUSIONS: This meta-analysis demonstrated the safety and efficacy of the Woven EndoBridge device in the management of ruptured aneurysms, but further studies are needed.

ABBREVIATION: APT = antiplatelet therapy

In recent years, the Woven EndoBridge device (WEB; MicroVention) has been increasingly used for the endovascular treatment of wide-neck aneurysms, particularly ruptured ones. One of the advantages of the WEB device in the treatment of ruptured intracranial aneurysms compared with other nontraditional techniques (ie, stent-assisted coiling or flow diversion) is that dual antiplatelet therapy is not necessary.1 A few series have detailed the use of the WEB device in patients with ruptured aneurysms. However, these studies are relatively small and represent early experience. To assess the technical success rate, effectiveness, safety, and early follow-up of patients with aneurysmal SAH treated with the WEB device in the acute phase, we performed a systematic review and meta-analysis of published series.

MATERIALS AND METHODS

Search Strategy

The literature was searched by a medical librarian for “Woven EndoBridge (WEB)” or “flow diverter” combined with “aneurysm” and its variants in accordance with the Preferred
Adequate occlusion was assessed according to the occlusion scale. A low risk of bias were identified as high-quality studies. Studies with a high and moderate risk of bias, and studies with low-quality studies included defined as midterm follow-up. Low-quality studies included the patients had been followed up for 1 year, 1-year follow-up, and procedure-related and overall mortality rates. If the patients had been followed up for >1 year, 1-year occlusion status was selected as the end point. Short-term follow-up was defined as <1-year follow-up, while ≥1-year follow-up was considered midterm follow-up. Low-quality studies included studies with a high and moderate risk of bias, and studies with a low risk of bias were identified as high-quality studies. Adequate occlusion was assessed according the occlusion scale mentioned in each study, which generally included complete aneurysm occlusion or small neck remnant. Data were also collected concerning anti-coagulation and antiplatelet use.

**Study Risk of Bias Assessment**

We used the Newcastle-Ottawa Quality Assessment Scale for case-control studies tool to assess the risk of bias in our included studies. Although this tool was designed for the comparative studies, we modified it, focusing on 5 questions: 1) Did the study include all patients or consecutive patients versus a selected sample; 2) was the study retrospective or prospective; 3) was angiographic and clinical follow-up satisfactory, thus allowing ascertainment of all outcomes; 4) were outcomes clearly reported; and, 5) were the operators treating the patients, the same ones who assessed angiographic and clinical outcomes?

**Statistical Analysis**

The cumulative incidence (event rate per patient at the end of the study) for each study was estimated, along with 95% confidence intervals. Because we anticipated marked heterogeneity in the populations and interventions across various included studies, a random effects model was used to pool incidence rates across studies. The I² statistic was used to express the proportion of inconsistency not attributable to chance. Analyses including subgroup meta-analysis were conducted using OpenMeta[Analyst] open-source statistical software (http://www.cebm.brown.edu/openmeta/).

**RESULTS**

**Study Selection and Characteristics**

After removing duplicates, we found 1701 articles. After we excluded non-relevant articles by the screening of the title and abstract, 69 articles were included for full-text screening. Eighteen studies (19 articles)1-21 were included in our qualitative and quantitative analyses. The results of 1 included study were published in 2 separate articles that had to be included to cover the total characteristics and outcomes of the sample.8,9 Overall, 487 patients with 496 aneurysms were considered. The mean age was 57 years; 387 (83.6%) and 76 (16.4%) of these aneurysms were located in the anterior (commonly in anterior communicating artery, MCA, and posterior communicating artery) and posterior (commonly in the basilar artery and PICA) circulations, respectively. The mean width of the ruptured aneurysms, reported in 10 studies, was 5.6 mm. The mean height of the ruptured aneurysms (consistently reported in 5 studies) was 6.0 mm. Most aneurysms were wide-neck. Two hundred seventy-five (74.7%) patients were admitted with Hunt and Hess scores of 1–3, and 93 patients (25.3%) experienced severe SAH (Hunt and Hess score, 4–5). Forty-one additional interventions, consisting mainly of coiling or stent placement, were used for incompletely occluded ruptured aneurysms. A summary of the data of the included studies and reported baseline characteristics of the ruptured aneurysms are provided in the Online Supplemental Data. The flow diagram for study selection is provided in the Online Supplemental Data.
**Primary Outcomes**

The primary outcome (aneurysm rerupture after treatment with the WEB device) occurred in 1.1% of cases (95% CI, 0.1%–2.1%) (4/423 aneurysms): 0.8% (95% CI, 0.3%–2%) and 1.7% (95% CI, 0.1%–3.5%) in the studies with short- and midterm follow-ups, respectively. The rate of rerupture per month during follow-up was 0.2% (95% CI, 0.0%–0.3%).

**Secondary Outcomes**

A total of 285 patients from 16 studies had angiographic occlusion outcomes reported. Adequate occlusion was achieved after short-term follow-up in 193 of 216 patients (91.7%; 95% CI, 87.4%–95.9%) and after midterm follow-up in 77 of 94 patients (77%; 95% CI, 68.6%–85.4%). In total, 245 patients showed adequate occlusion (87.3%; 95% CI, 82.1%–92.4%) at last follow-up. Adequate occlusion was reported in 78.1% (95% CI, 69.4%–86.8%) among studies with high quality (low risk of bias) and 93.4% (95% CI, 90%–96.9%) among studies with low quality (high or moderate risk of bias). The mean length of follow-up ranged from 3 to 15 months, with a median of 7 months. During follow-up, 27 aneurysms required retreatment (5.1%; 95% CI, 3%–7.3%), 5.8% (95% CI, 2.8%–8.7%) at short-term and 6% (95% CI, 1.2%–10.9%) at midterm follow-up. The treatment-related perioperative complication rate was 13.2% (95% CI, 9.2%–17.1%). Only a minority of these complications (24.4%; 95% CI, 14.5%–34.3%) resulted in prolonged clinical deterioration or permanent neurologic deficits; thus, the overall clinical complication rate related to WEB device deployment was 3.2% (95% CI, 1.6%–4.7%), 13 hemorrhagic (2%; 95% CI, 0.8%–3.3%) and 41 thromboembolic (6.8%; 95% CI, 4.6%–9%) complications. At short- and midterm follow-up, 210 of 250 patients (85%; 95% CI, 78%–92.1%) and 55 of 64 patients (86.7%; 95% CI, 78.5%–95%) showed favorable clinical outcomes (mRS 0–2), respectively. Twelve patients died in the perioperative period as a result of procedure-related complications (2.1%; 95% CI, 0.8%–3.3%). The all-cause mortality rate was 11.5% (95% CI, 7%–16%).

**Antiplatelet Therapy**

Routine antiplatelet therapy (APT) was not used in 10 included studies, while in 8 studies, APT was routinely given before and after the procedure either as monotherapy or dual therapy for variable time intervals. Many studies reported the use of dual antiplatelet therapy for 1–2 months in cases in which a thromboembolic complication occurred or an additional device was deployed. In those who received any APT, the rate of thromboembolic and treatment-related overall complications was 7.4% (95% CI, 3.2%–11.5%) and 14.3% (95% CI, 6.1%–22.4%), respectively. In studies in which no routine APT was used, the rates of thromboembolic and treatment-related overall complications were 6.5% (95% CI, 4%–9.1%) and 13.1% (95% CI, 8.5%–17.7%), respectively. The procedure-related primary and secondary outcomes and details of the APT use are explained in the Online Supplemental Data. The forest plots of the meta-analysis of the outcomes are shown in the Figure and the Online Supplemental Data.

**Risk of Bias**

Of 18 studies, the risk of bias was low in 5, moderate in 10, and high in 3 studies. The smallest study had 5 patients with 5 ruptured aneurysms, and the largest study included 100 patients with 106 aneurysms (100 ruptured aneurysms).

**DISCUSSION**

This systematic review and meta-analysis of 18 cohort studies demonstrates that primary treatment of ruptured intracranial aneurysms with the WEB device is both safe and effective, with rerupture rates of approximately 1% and a perioperative complication rate of 13%, with most of these not resulting in additional clinical deficits. At long-term follow-up, >85% of the aneurysms showed adequate obliteration, suggesting that in general, the obliteration rate of ruptured aneurysms treated with the WEB device is high. These findings are important because they suggest that the WEB device could potentially be used routinely in the treatment of ruptured wide-neck bifurcation aneurysms.

One commonly used technique for the treatment of wide-neck bifurcation aneurysms is stent-assisted coiling. Several series have recently been published examining the efficacy of stent-assisted coiling in the treatment of ruptured aneurysms. In a recently published meta-analysis by Bsait et al., the rates of postinterventional rebleeding (2.5%) and hemorrhagic complications (8.7%) were higher than the rates of these complications in the setting of WEB device deployment according to our meta-analysis. The risk of thromboembolic complications in the meta-analysis of Bsait et al was 9.1%, and this is also higher than that found in our study (6.8%). Another meta-analysis published in 2019 compared the rate of perioperative complications for ruptured intracranial aneurysms treated with stent-assisted coiling with the rate of those treated with simple coiling and reported a 20.2% complication rate for the stent-assisted coiling group versus 13.1% for the coiling-only group. Nevertheless, the rate of perioperative complications in our meta-analysis was lower (13.2%) than that in the stent-assisted coiling group and similar to the that in the coiling group. Thus, intrasaccular flow-diversion treatment with the WEB may be safer than stent-assisted coiling and as safe as primary coiling for treating wide-neck bifurcation aneurysms.

Prevention of rebleeding is the primary goal in the treatment of ruptured aneurysms. The rate of rebleeding in our meta-analysis is similar to that reported in the Analysis of Recanalization after Endovascular Treatment of Intracranial Aneurysm (ARETA) study, a large prospective, multicenter study conducted to assess the recanalization of ruptured intracranial aneurysms after endovascular treatment with coiling and balloon-assisted coiling. The risk of rebleeding in 753 patients with ruptured aneurysms in the ARETA study was 1% (95% CI, 0.3%–1.7%). These patients had 78 thromboembolic (10.4%) and 28 hemorrhagic (3.7%) complications, similar to the results of our study. In the International Subarachnoid Aneurysm Trial (ISAT), 1073 patients underwent coil embolization for ruptured aneurysms. The rate of rebleeding was 1.9% in the first 30 days after the treatment and 0.8% at follow-up (30 days to 1 year); 92% of aneurysms showed adequate occlusion (66%, complete occlusion; 26%, neck remnant or subtotal occlusion), and the overall
FIGURE. A, Forest plot with a random effects model shows the late rebleeding rate. B, Forest plot with a random effects model shows the rate of treatment-related perioperative complications grouped by APT use. C, Forest plot with a random effects model shows the rate of thromboembolic complications grouped by APT use. Ev/Ttrt indicates Event (Outcome, complication)/Treated patient.
mortality rate after 1 year was 8.1%. In comparison with ISAT, in our meta-analysis, the overall rebleeding (1%) and adequate occlusion (87%) rates were similar, an outcome especially remarkable given that the aneurysms treated with the WEB device were mostly wide-neck. The overall mortality rate (11.5%) was slightly higher. Nevertheless, 25% of our study patients were admitted with severe SAH compared with 12% in ISAT, and procedure-related mortality was around 2%. From these results, we can infer that the WEB may be as safe as simple coiling and balloon-assisted coiling to treat acutely ruptured intracranial aneurysms.

One interesting issue that has been brought up recently is whether there are differences in occlusion rates and clinical outcomes between ruptured and unruptured aneurysms treated with the WEB. In a study published by Pierot et al, which included cumulative data from 3 clinical trials comprising >90% unruptured aneurysms (WEB Clinical Assessment of Intrasaccular Aneurysm Therapy [WEBCAST], WEBCAST-2, and the French Observatory), the rate of adequate occlusion at 1 year was found to be 79.1%, which is similar to the adequate occlusion rate (77%) of ruptured aneurysms at midterm follow-up in our meta-analysis. In the WEBCAST study, 85.4% of the treated unruptured aneurysms had adequate occlusion at short-term follow-up (6 months), which is only slightly less than that in our study of ruptured aneurysms (91.7%). This can be referred to as thrombogenic milieu in the setting of SAH that may accelerate aneurysm thrombosis.

The rate of retreatment in unruptured aneurysms at 1-year follow-up was 6.9%, which is also similar to that in our study (6%). Thromboembolic adverse events occurred in 14.4% of the patients in the cumulative data of Pierot et al, which is twice as high as that in our results (6.8%). However, the symptomatic thromboembolic events with clinical sequela were reported as 3%, which is similar to the rate (3.2%) of overall clinical complications in our meta-analysis. Furthermore, the rate (2%) of hemorrhagic complications in this study is also similar to that in the previous study with unruptured aneurysms (1.8%). These results demonstrate that the WEB device has a high efficacy and feasibility in the management of ruptured wide-neck cerebral aneurysms, similar to what was confirmed in the past for unruptured wide-neck aneurysms.

The main advantage of using the WEB device over stent or flow-diversion techniques is the absence of the requirement for periprocedural dual antiplatelet treatment. This is especially important in the acute phase of aneurysmal SAH when patients often require invasive procedures such as placement of external ventricular drains or lumbar drains and ventriculoperitoneal shunts, procedures that can be complicated by hemorrhage in the setting of dual antiplatelet therapy. While there was no notable difference in thromboembolic (non-APT, 6.5%; APT, 7.4%) and overall complication (non-APT, 13.1%; APT, 14.3%) rates between patients with and without routine nonuse of antiplatelet therapy in our meta-analysis, at our center, we continue to place these patients on antiplatelet therapy with high-dose aspirin and clopidogrel (Plavix) because we believe that this prevents severe acute thrombosis after WEB device placement in ruptured aneurysms.

**Limitations**

All the included studies in this meta-analysis were uncontrolled, and many of them were retrospective and single-center. Thus, our meta-analysis is limited by selection bias and the heterogeneity that arises from the variability in aneurysm morphologies, patient scenarios, operator experience, and practice protocols (eg, pre- and postoperative antiplatelet therapy application methods). Despite our effort to exclude overlapping patient populations, the possibility of overlap in patients among the studies remains. The mean follow-up periods among the included studies were variable and modest in terms of length. However, we tried to reduce this variety by selecting the last follow-up point or 1-year follow-up results. Most of the studies in the literature lack the stratification of outcomes based on aneurysm rupture status. Among those that investigated outcomes on the basis of the rupture status, many did not report the impact of important variables such as the type and size of the WEB device and baseline patient morbidity in the treatment outcomes. The rate of adequate occlusion in studies with low quality, mostly due to self-assessment of the angiographic and clinical outcomes, was higher (93.4%) than that of high-quality-studies (78.1%). This finding raises the question of bias that results from including such low-quality studies. Furthermore, the relatively small sample of patients with reported angiographic outcomes, absence of a single and common standard method for assessment of aneurysm occlusion, lack of a control group, and the short duration of follow-up may affect the reliability of the results concerning the safety and durability of aneurysm occlusion. Therefore, the overall certainty in the evidence at present is rated as low. Finally, this meta-analysis has concentrated on only ruptured aneurysms, which can be a limitation. However, the main advantage of this meta-analysis was the thorough assessment of WEB device efficacy and safety in acute subarachnoid hemorrhage situations.

**CONCLUSIONS**

Our meta-analysis of 18 studies including around 500 ruptured aneurysms treated with the WEB device demonstrated the safety and efficacy of the WEB device in the management of wide-neck ruptured aneurysms. Further studies and randomized clinical trials with longitudinal follow-up directly comparing the WEB with other established techniques (ie, coiling, clipping, stent-assisted coiling, and so forth) are needed.
