ABSTRACT

BACKGROUND AND PURPOSE: Forced respirations reportedly have an effect on CSF movement in the spinal canal. We studied respiratory-related CSF motion during normal respiration.

MATERIALS AND METHODS: Six healthy subjects breathed at their normal rate with a visual guide to ensure an unchanging rhythm. Respiratory-gated phase-contrast MR flow images were acquired at 5 selected axial planes along the spine. At each spinal level, we computed the flow rate voxelwise in the spinal canal, together with the associated stroke volume. From these data, we computed the periodic volume changes of spinal segments. A phantom was used to quantify the effect of respiration-related magnetic susceptibility changes on the velocity data measured.

RESULTS: At each level, CSF moved cephalad during inhalation and caudad during expiration. While the general pattern of fluid movement was the same in the 6 subjects, the flow rates, stroke volumes, and spine segment volume changes varied among subjects. Peak flow rates ranged from 0.60 to 1.59 mL/s in the cervical region, 0.46 to 3.17 mL/s in the thoracic region, and 0.75 to 3.64 mL/s in the lumbar region. The differences in flow rates along the canal yielded cyclic volume variations of spine segments that were largest in the lumbar spine, ranging from 0.76 to 3.07 mL among subjects. In the phantom study, flow velocities oscillated periodically during the respiratory cycle by up to 0.02 cm/s or 0.5%.

CONCLUSIONS: Respiratory-gated measurements of the CSF motion in the spinal canal showed cyclic oscillatory movements of spinal fluid correlated to the breathing pattern.

ABBREVIATION: SSAS = spinal subarachnoid space

Respirations reportedly have an effect on CSF movement in the spinal subarachnoid space (SSAS), which is also known to undergo a cardiac-driven oscillatory motion1-4 associated with the periodic changes in intracranial pressure, superposed on a steady motion resulting from secretion of CSF by the choroid plexus in the ventricles on the one hand and steady-streaming effects appearing as small nonzero time averages of oscillatory components on the other hand. Whereas steady secretion by the choroid plexus results in slow craniocaudal spinal fluid flow,5,6 commonly known as bulk flow, steady-streaming results in closed recirculating regions caused by the variation of anterior-posterior SSAS size along the spine7-9 or localized anatomic features such as nerve roots.10 Forced respirations have been shown to produce oscillatory motion of the CSF at a slower cycling rate than the cardiac cycle, both in the spine and the brain.11-26 Most previously published observations on spinal CSF flow during respiration have used real-time MR imaging, short acquisitions, and forced or deep breathing, coughing, or sniffing.11-24 In previous reports, the forced respiratory efforts produced both cranio-caudal and caudo-cranial CSF movements along the entire spinal canal and especially in the lower thoracic segment. In some experiments, forced inspiration and expiration apparently were the major factors in spinal fluid flow.14,16,20,21,24,25 The effect...
of normal breathing on spinal CSF flow has recently been studied, but only at the foramen magnum, where it was found to play a lesser role compared with cardiac-driven motion.

A detailed analysis of CSF movement along the length of the spinal canal related to normal breathing has not, to our knowledge, been published. An improved quantitative knowledge of respiratory effects on CSF flow will enhance our understanding of CSF dynamics, which is key in the characterization of nutrient movement and waste product clearance in the subarachnoid spaces and the distribution of drugs injected intrathecally.

We planned a study to quantify respiratory-related CSF motion along the length of the spinal canal during breathing at a normal rate and depth. We developed a method of maintaining a constant respiratory rhythm during flow data acquisition and used a respiratory-gated MR imaging acquisition, which achieves greater temporal and spatial resolution than the real-time MR imaging acquisition used in previous studies. We acquired flow data at multiple spinal levels to characterize, as completely as possible, the effects of normal breathing on fluid movement along the length of the spinal canal.

**MATERIALS AND METHODS**

**Subjects**

Six subjects (2 women, 4 men; age range, 27–53 years; weight range, 50–82 kg; and height range, 160–175 cm) with good health, normal pulse and respiratory rates, no spinal disorders, and no contraindications to MR imaging were enrolled for MR imaging data collection at the Mind, Brain and Behavior Research Center of the University of Granada and analysis of CSF flow. The study was approved by the institutional review board of the Universidad de Granada, and written informed consent was obtained from each subject before MR imaging. The MR images obtained in the subjects were reviewed by a neuroradiologist to exclude spinal pathologies.

**Study Design**

Each subject was instructed to breathe guided by a video showing a sine wave with a frequency at the subject’s previously determined normal breathing rate (15–18 breaths per minute in the 6 subjects). Subjects were fitted with a thoracic circumference monitoring belt and asked to inhale and exhale normally to match the chest diameter to the sine wave, achieving inspiration and expiration of equal duration. Each subject practiced breathing to the visual guide for a period of time before imaging. For imaging, conventional T1- and T2-weighted images of the entire spine were obtained in each subject, and flow measurements were acquired at 5 locations along the spinal canal: C2/C3, T2/T3, T6/T7, T10/T11, and L1/L2 (Fig 1).

**MR Imaging Measurements**

All imaging was performed on a 3T Magnetom Prisma Fit MR imaging scanner (Siemens) using a 64-channel head and neck coil and a 32-channel spine coil. High-resolution, whole-spine images were obtained using a 3-block sagittal 3D T2 SPACE sequence, and flow measurements were acquired with a 2D phase-contrast MR imaging sequence at 5 locations along the spinal canal: C2/C3, T2/T3, T6/T7, T10/T11, and L1/L2 (Fig 1-B).
Changes Due to Respiration

Quantification of the Flow Rate and Spinal Canal Volume Changes Due to Respiration

An in-house-developed Matlab code (MathWorks) was used to postprocess the MR phase and magnitude measurements and to obtain the in-plane velocity distribution of velocity $U$ in the SSAS at each spinal level (Fig 2A), the location of which has a distance $x_i$ along the spinal canal to the foramen magnum (Fig 1B). At each level, the ROIs corresponding to the SSAS were drawn manually (Fig 1B). By numerically integrating the velocity over these ROIs, the volume flow rates across each location ($Q(x_i, t) = \int_{R} U dA$) were obtained as a function of time $t$ (Fig 2B). The results were filtered with a 5-point moving mean (Fig 2C). Stroke volume was calculated for each level by numerically integrating the flow rate over the respiratory cycle, $V_i(x) = 0.5 \int_0^T |Q(x, t)| dt$ (Fig 2E). The instantaneous change in volume of each spine segment, with respect to the start of the inhalation cycle, was computed as the integral of the difference in flow rates across the spinal levels that delimitate the segment, $\Delta V_{i\rightarrow i+1}(t) = \int [Q(x_i, t) - Q(x_{i+1}, t)] dt$ (Fig 2D). The net volume change over inhalation and exhalation (Fig 2E, F) for each segment was calculated as $\Delta V_{i\rightarrow i+1}(t_{1/2}) = \Delta V_{i\rightarrow i+1}(0)$ and $\Delta V_{i\rightarrow i+1}(T) = \Delta V_{i\rightarrow i+1}(t_{1/2})$, where $t_{1/2}$ corresponds to the instant in time at the end of inhalation and the start of exhalation, defined as the point where $Q(x_i, t)$ crosses zero, so that $t_{1/2} \approx T/2$.

Evaluation of Magnetic Susceptibility Artifacts in In Vivo Flow Measurements

A phantom was used to quantify the effect of magnetic susceptibility changes in the FOV induced by the thoracic motion on velocity data measured with phase-contrast MR imaging. The phantom contained a closed hydraulic circuit composed of a straight tube of constant diameter equal to 2.2 cm, a pump, and a mass flow meter. Tap water with a T1 of 2.7 seconds to simulate CSF, which has a T1 relaxation time of about 3 seconds, was pumped through the phantom at a constant flow rate. Respiratory-gated MR imaging flow measurements were obtained of the phantom with and without a subject lying supine on the phantom. Data were acquired at 2 locations, T6/T7 and L1/L2, with the same MR imaging parameters and protocols as used for imaging the subjects.

RESULTS

MR imaging showed no evidence of spinal pathology in the 6 subjects. All subjects breathed with a sinusoidal pattern closely approximating their normal respiratory volumes. Flow measurements were obtained from MR imaging measurements successfully in all subjects and selected spinal locations. Aliasing artifacts were encountered in 2 subjects for 2 spinal levels and were corrected accordingly. We first describe the results for subject 1 in detail (Fig 2) and then compare results in the 6 subjects (Fig 3).
In subject 1, the respiratory-gated flow was caudocranial during inhalation and craniocaudal during exhalation at all spinal levels. Velocity fields (Fig 2A) taken mid-inhalation and mid-exhalation showed that CSF flow is uniformly distributed over the cross-sectional area of the SSAS, with peak velocities ranging from 5 to 8 cm/s. The corresponding volume flow rates $Q_{x_i}(t)$ (Fig 2B–C) confirmed that the directionality of the flow was in phase with inhalation and exhalation and differed in phase by 180°. Flow volume rates between inspiration and expiration differed by <10%.

The largest volume of flow rate was observed at L1/L2 (2 mL/s). The concomitant stroke volume, $V_s$ (Fig 2E), which is a measure of the volume of CSF that passes through L1/L2 at this location, was 1.75 mL. Cranially from L1/L2, the stroke volume progressively decreased toward the foramen magnum (minimum, $V_s$ of 1 mL). Above the L1/L2 level, the stroke volumes were <0.5 mL. Caudally from L1/L2, the stroke volume diminished to zero. The largest variation of CSF volume was found in the stretch of canal between the L1/L2 level and the caudal end of the canal. The corresponding total accumulation and depletion of CSF between the start and end of inhalation (Fig 2E) and between the start and end of exhalation (Fig 2F) were equal.

The general trends described for subject 1 are evident in all subjects (Fig 3), though large subject-to-subject variations were found. During inspiration, caudocranial CSF flow was induced, and during exhalation, craniocaudal flow. The velocity fields during inhalation were found to be comparable in magnitude with those during exhalation at all spinal levels. Correspondingly, the volume of flow rates during inhalation (Fig 3C) were similar in magnitude to those during exhalation. The variation in stroke volume (red dots in Fig 3E–G) generally was largest in the lower lumbar region and least in the cervical region, except in 1 subject (subject 4). Peak flow rates ranged from 0.60 to 1.59 mL/s in the cervical region, 0.46 mL/s to 3.17 mL/s in the thoracic region, and 0.75 mL/s to 3.64 mL/s in the lumbar region. Differences in flow rates are correlated to differences in stroke volume and, consequently, to the increase or decrease in CSF volume. The Table summarizes the minimum, mean, and maximum observed stroke volumes and volume changes along the spinal canal. The increase or decrease in CSF volume (Fig 3D) was largest in the lumbar region.

In the phantom study of respiratory-induced artifacts in flow measurements, flow velocities measured in the phantom under a supine subject breathing typically deviated periodically during the respiratory cycle by up to 0.02 cm/s for all flow velocities tested.
which ranged from 0 to 15 cm/s. The deviations did not exceed 0.5% of the mean velocities tested.

**DISCUSSION**

Respiratory-gated measurements of the CSF motion in the spinal canal during normal rates and volumes of respiration showed cyclic oscillatory movements of spinal fluid correlated to the breathing pattern. The stroke volume, an integral measure of how much fluid moves across a certain spinal section over the course of 1 respiratory period, was, on average, largest in the lower thoracic and upper lumbar spine, decreasing cranially up to 35% toward the foramen magnum and caudally toward the distal end, where it vanished. The concomitant net volume variation was found largest at the upper lumbar-sacral segment and considerably lower elsewhere. This finding indicates the volume variation of the subarachnoid space near the thoracolumbar junction through the respiratory cycle as the main effect of respiration. The minimum and maximum measured values of stroke volume and net volume change in the Table reveal large interindividual differences.

The results of this study agree qualitatively with those in previous studies in which spinal fluid was found to move cranially during inspiration and caudally during expiration. The effect of normal, sustained breathing was reported to induce peak velocities of approximately 1.3 cm/s at the foramen magnum, compared with 5 cm/s for subject 1 at C2/C3 in our results. Studies that reported the spatial distribution of respiratory-induced flow along the spinal canal mostly considered forced respiration or breathing maneuvers such as coughing or sniffing. In agreement with our findings, the largest respiration-induced flow rates occurred at the upper lumbar spinal level. Flow rates and associated stroke volumes greater than ours were measured, consistent with the use of more forceful respiratory efforts. For example, the mean stroke volumes corresponding to forced breathing compared with those of the present study under normal breathing are 2.4 versus 1.0 mL at C2/C3, 1.6 versus 1.1 mL at T6/T7, 6.7 versus 1.5 mL at T10/T11, and 2.0 versus 1.5 mL at L1/L2, respectively. The maximum associated net volume variation over inspiration or exhalation occurred in the caudal half of the spinal canal. For forced breathing, the maximum was found in the segment between T6 and T10 (mean, 5.1 mL), whereas for the present work, it occurred in the lumbar segment between L1/L2 and the sacral end (mean, 1.5 mL). Previous studies have hypothesized that the nonuniform compliance of the SSAS is coupled to the extraspinal paravertebral venous plexus. Furthermore, forced respiratory effort induced a nonzero net CSF flow. On the contrary, our data, acquired over multiple minutes of normal breathing, showed no net flow, consistent with conservation of total spinal CSF volume over the course of the experiment. We are not aware of any previously reported detailed CSF flow measurements at multiple spinal levels during normal respiration.

Respiratory-driven spinal CSF flow occurs in addition to that driven by the cardiac cycle. Induced by intracranial pressure fluctuations, the cardiac-driven flow presents a different spatial variation of flow rate and stroke volume along the spine (eg, Figs 2 and 3 in Sincomb et al) with maximum values in the upper cervical region, decreasing monotonically toward the closed caudal end. Given the large subject-to-subject variations in observed respiratory-driven flow, comparisons between cardiac- and respiratory-driven flow should be conducted on a subject-to-subject basis. As an example, subjects 1 and 2 in Sincomb et al, correspond to subjects 5 and 2 of the present study. For these subjects, the ratios between respiratory- and cardiac-driven peak flow rates were, respectively, 0.1 and 0.3 at C2/C3, 0.2 and 0.4 at T6/T7, and 0.7 and 1.3 at L1 and L2, where both peak values become comparable. Nevertheless, because the respiratory cycle is approximately 3.5 times longer, the associated stroke volumes become dominant in the lower spine. In particular, the ratios between the respiratory- and cardiac-driven stroke volumes for subjects 5 and 2 are respectively 0.8 and 1.2 at C2/C3, 1.1 and 1.6 at T6/T7, and 4.9 and 7.3 at L1/L2. Future work should confirm these trends.

Our study had a small number of subjects, with an age range of 26 years. The analysis should be extended in the future to a larger number of subjects with greater anatomic variations to investigate reproducibility and determine the origin of the large interindividual differences. The influence of subject posture, which has been conjectured to influence cardiac-driven steady-streaming CSF flow, was not studied here. Furthermore, the duration of inhalation and exhalation was equal, which might not be reflective of normal breathing. The study should be extended to further evaluate the effect of different respiration modes on the CSF motion. Finally, small experimental errors might be expected from the limited accuracy of phase-contrast MR measurements of slow flow and from the section orientation not being perfectly perpendicular to the axis of the spinal canal.

This study shows that respiration affects CSF flow, especially in the lower thoracic and lumbar spine. The total pulsating motion of the CSF in the SSAS is the sum of the cardiac- and respiratory-driven components. The cardiac-driven flow exhibits near-zero velocities in the lumbar region, much smaller than those associated with the respiratory-driven flow measured here, so that respiration is the main driving mechanism in the lumbar

spine. Consequently, the respiratory cycle may be a factor in the movement of drugs and anesthetics administered intrathecally. Modeling of CSF movement and drug transport must take into consideration the effect of respiration.

CONCLUSIONS
Normal respiration in healthy subjects induces CSF motion in the spinal canal, which is directed caudocranially during inhalation and cranio-caudally during exhalation. Compared with cardiac-driven CSF flow, respiratory-driven flow dominates in the lumbar region. Respiration constitutes, therefore, an important driving mechanism of CSF. Patient-specific analyses of cardiac-driven and respiratory-driven CSF flow and anatomic measurements in combination with complementary mathematic models can help improve the effectiveness and predictability of intrathecal drug delivery treatments in the future.
