ABSTRACT

SUMMARY: There is increasing use of neuroimaging modalities, including PET, for diagnosing dementia. For example, FDG-PET demonstrates hypometabolic regions in the posterior cingulate gyri, precuneus, and parietotemporal association cortices, while amyloid PET indicates amyloid deposition in Alzheimer disease and mild cognitive impairment due to Alzheimer disease. Furthermore, the use of combination PET with structural MR imaging can improve the diagnostic accuracy of dementia. In other neurodegenerative dementias, each disease exhibits a specific metabolic reduction pattern. In dementia with Lewy bodies, occipital glucose metabolism is decreased, while in frontotemporal dementia, frontal and anterior temporal metabolism is predominantly decreased. These FDG-PET findings and positive or negative amyloid deposits are important biomarkers for various neurodegenerative dementias.

ABBREVIATIONS: Aβ = amyloid β peptide; AD = Alzheimer disease; APOE = apolipoprotein E; CBD = corticobasal degeneration; DLB = dementia with Lewy bodies; FTD = frontotemporal dementia; MCI = mild cognitive impairment; PD = Parkinson disease; PiB = Pittsburgh compound-B; PSP = progressive supranuclear palsy; VBM = voxel-based morphometry

The number of patients with dementia is progressively increasing worldwide. Dementia is a clinical diagnosis based on significant and persisting deficits of intellectual function, usually memory. Diagnostic imaging techniques for morphologic examinations (eg, CT and MR imaging) and for functional examinations (eg, SPECT and PET) are now used widely for supporting the diagnosis of dementia. Such imaging techniques can indicate the likely underlying pathology in a patient who meets the clinical criteria for dementia. In particular, amyloid imaging PET has been reported to show the pathophysiologic states of dementia. The PET radiopharmaceutical [18F]fluorodeoxyglucose can detect regional glucose metabolism in patients with dementia and is the most widely available and useful biomarker for dementia diagnosis. However, to exclude several pathologies such as subdural hematoma, vascular dementia, normal pressure hydrocephalus, and brain tumors, clinical examination is first performed by using MR imaging because FDG-PET alone cannot detect these diseases. After this process, FDG-PET is then performed to detect early neurodegenerative dementia, differentiate neurodegenerative dementias, or suggest comorbidity of other neurodegenerative diseases. Herein, I review the various imaging approaches for dementia, with a particular focus on PET and new techniques or tracers.

Alzheimer Disease

Alzheimer disease (AD) is the most common dementia, which starts with impairment of memory followed by multiple domains of cognitive dysfunction. The 2011 criteria for AD2,3 was revised from that in 1984,4 and the recommendations regarding the respective roles of FDG-PET and MR imaging in AD and mild cognitive impairment (MCI) are conflicting. However, PET plays an important role as a biomarker in AD, as well as for functional and molecular imaging. For example, FDG-PET is described as a “neuronal injury” biomarker in AD.2,3

FDG-PET in Alzheimer Disease

FDG-PET can demonstrate a glucose metabolic reduction in the parietotemporal association cortices, posterior cingulate, and precuneus regions at the early stage of AD (Fig 1). By contrast, in the healthy elderly brain, posterior cingulate glucose metabolism is much higher than that in other cortices, while parietal glucose metabolism is the same as that in the primary sensorimotor cortices (Fig 2). In the moderate-to-severe stages of AD, hypometabolic regions spread to the frontal association cortices, while metabolism in the striatum, thalamus, primary sensorimotor cortices, visual cortices, and cerebellum are relatively preserved despite disease progression.

Because the magnitude of glucose metabolic reduction in the medial temporal lobe, including the hippocampus, is not as large...
as that in the parietotemporal or posterior cingulate cortices, a
decrease in hippocampal glucose metabolism with progression
from mild-to-moderate-stage AD is not usually demonstrated,\(^5\)
despite obvious hippocampal atrophy at the early stage. Hip-
pocampal glucose metabolism is somewhat decreased at the early
stage of AD. However, it is difficult to detect the small reduction of
hippocampal glucose metabolism in patients with early AD be-
cause the hippocampal glucose metabolism is smaller than the
neocortical glucose metabolism, even in healthy subjects, and the
magnitude of the decrease is modest. Thus, a method for detecting
hippocampal metabolic reduction at an early stage of AD is re-
quired.\(^6,7\) However, Karow et al\(^9\) reported that FDG-PET has the
same sensitivity as MR imaging for detecting brain degeneration
in preclinical and mild AD, suggesting that MR imaging may be a
more practical clinical biomarker for early detection of AD.

**Mild Cognitive Impairment Due to Alzheimer Disease**

Mild cognitive impairment consists of a heterogeneous pathol-
ogy, and MCI due to AD is a transitional stage between aging and
AD. MCI due to AD demonstrates the same glucose-reduction
pattern as early AD (Fig 3), which predicts that the patient will
show symptoms of AD in the near future. At the early stage of AD
or MCI due to AD, it is difficult to detect the characteristic hypometa-
bolic patterns on FDG-PET images by visual inspection. As such,
statistical images are helpful. Nevertheless, FDG-PET generally has a
higher accuracy than MR imaging for diagnosing early AD\(^10,11\) and

---

**FIG 1.** A patient with early Alzheimer disease, 77 years of age, Mini-
Mental State Examination score = 25. A, Minimal atrophy was seen in
the right hippocampus. B, FDG-PET shows reduced glucose metabol-
ism in the bilateral parietotemporal association cortices and poste-
rrior cingulate gyri and precuneus. C, PiB accumulations are demon-
strated in the cerebral cortices except for the occipital and medial
temporal regions. Medial parietal and frontal accumulations of PiB are
high, indicative of positive amyloid deposit.

---

**FIG 2.** Healthy elderly male subject, 78 years of age, Mini-Mental
State Examination score = 30. A, A slight enlargement of the right
inferior horn of the lateral ventricle is seen on the T1-weighted MR
image. B, The regional glucose metabolism is not reduced on the
FDG-PET images. Note that the posterior cingulate glucose metabo-
lism is much larger than that in other regions. C, PiB-PET shows non-
specific accumulation in the white matter but no PiB accumulation in
the gray matter. The amyloid deposit is negative.

---

**FIG 3.** MCI due to AD. Regions exhibiting a significant reduction in
glucose metabolism in patients with MCI due to AD (\(n = 20\)) com-
pared with healthy elderly subjects (\(n = 20\)) are demonstrated by
statistical parametric maps. Bilateral parietal and posterior cingulate
metabolism is decreased in patients with MCI due to AD. These de-
creased regions are the same as those in patients with early AD.

---

for predicting rapid conversion of MCI to early AD.\(^12\) A combination
of PET and other biomarkers is important because imaging and CSF
biomarkers can improve prediction of conversion from MCI to AD
compared with baseline clinical testing. FDG-PET appears to add the greatest prognostic information.13-16

Effects of APOE on FDG-PET and Amyloid Imaging of Alzheimer Disease

The apolipoprotein E gene (APOE) is a risk factor for late-onset AD, while the APOE e4 allele (e4) increases the risk and decreases the average age of dementia onset. Patients with early-onset AD who were APOE e4-positive showed a significant decrease in glucose metabolism in the medial temporal lobe compared with patients with APOE e4-negative AD.17 By contrast, in the late-onset group, there were no differences in the glucose-metabolic reduction patterns between patients with APOE e4-positive and –negative AD. A similar pattern of cerebral hypometabolism was also detected between patients with APOE e4-positive and –negative AD but with stronger abnormalities in e4 carriers in the parietal, temporal, and posterior cingulate cortical regions. 18 Recently Ossenkoppele et al19 found a reversed APOE e4 dose effect for amyloid deposition in the frontal lobe, whereas APOE e4 carrier was associated with more profound metabolic impairment in the posterior parts of the cortex. These findings suggest that the APOE genotype has a differential effect on the distribution of amyloid plaques and glucose metabolism.

Statistical Voxel-Based Analysis Approach for Alzheimer Disease Diagnosis

Minoshima et al20,21 first developed the 3D stereotactic surface projection system (3D-SSP; http://www.rad.washington.edu/research/research/groups/nbl/neurostat-3d-ssp) and used z score images to aid visual inspection of individual FDG images for diagnosing AD (Fig 4). The Statistical Parametric Mapping program (Wellcome Department of Imaging Neuroscience, London, UK) was developed as a tool for analysis of PET and functional MR imaging images. For automatic diagnosis, Herholz et al22 proposed the t-sum method of calculating the total t-values in a region-of-interest template by using the Statistical Parametric Mapping program; by using this method, the parietotemporal and frontal regions were found to be AD-specific compared with healthy elderly subjects. An automatic diagnosis system by using 3D-SSP and a region-of-interest template was proposed for discriminating those with early AD from healthy subjects.23,24 This system was also applied to distinguish patients with dementia with Lewy bodies (DLB) from those with AD.24 All these systems require a database of healthy controls. More recently, however, a data base–independent system was proposed by using t-statistics between parietal and sensorimotor glucose metabolism in individual subjects.25 Mevel et al26 proposed an automatic system for determining hippocampal metabolism by using a voxel-based method and partial volume correction, which was useful in detecting MCI.

Combination of MR Imaging and PET

Most of the studies described above have focused on only a single technique such as structural MR imaging or PET. Yuan et al12 performed a meta-analysis and meta-regression on the diagnostic performance data for MR imaging, SPECT, and FDG-PET in subjects with MCI and reported that FDG-PET performed slightly better than SPECT and structural MR imaging in the prediction of conversion to AD in patients with MCI, while a combination of PET and structural MR imaging improved the diagnostic accuracy of dementia. Kawachi et al10 also compared the diagnostic performance of FDG-PET and voxel-based morphometry (VBM) on MR imaging in the same group of patients with very mild AD and reported an accuracy of 89% for FDG-PET diagnosis and 83% for VBM–MR imaging diagnosis, while the accuracy of combination FDG-PET and VBM-MR imaging diagnosis was 94%. These studies suggest that a combination of imaging modalities may improve the diagnosis of AD.

Amyloid Imaging in Alzheimer Disease

The most widely used tracer for amyloid imaging is 11C-Pittsburgh compound-B (PiB),27 which has a high affinity to amyloid β peptide (Aβ) aggregiates. The 11C-BF 227 ligand is also used for amyloid imaging,28 though its uptake contrast between amyloid-positive and -negative brain tissue is not as high as that for PiB, and it is used only at a few institutions in Japan. Because the

FIG 4. Process of voxel-based statistical maps. Original FDG-PET image of a patient with mild AD (A) is analyzed by using the 3D-SSP program, and the 3D-SSP surface map and z score map are produced. The z score map shows the regions with significantly reduced metabolism compared with a normal data base (B), which aid in the diagnosis of AD.
half-life of the $^{11}$C isotope is short, $^{11}$C-PiB is available only in specific institutions that have a cyclotron and a synthesis system. Conversely, the half-life of the $^{18}$F isotope is 110 minutes, and $^{18}$F-labeled amyloid imaging tracers will become widely used following production by radiopharmaceutical companies. Currently there are a few $^{18}$F-labeled amyloid imaging tracers available (Table 1), though in 2012, $^{18}$F-AV-45 (florbetapir) was approved by the FDA for PET imaging of $\beta$-amyloid neuritic plaques in the living brain. $^{18}$F-AZD4694 is also expected to be a good radioligand for both diagnostic use and evaluation of disease-modifying therapies in AD.

Amyloid PET is helpful in the diagnosis of AD. However, the timing of amyloid accumulation is at a preclinical stage of AD. Early $\beta\A$ accumulation and increased vulnerability to $\beta\A$ pathology play critical roles in the pathogenesis of patients with early-onset AD. $\beta$ deposition initiates the pathologic cascade but is not the direct cause of cognitive impairment, and intermediate $\beta$ deposit may represent individuals with $\beta$ coexistent with other pathologies. Furthermore, amyloid deposit is not unique to AD and can be found in other diseases or healthy elderly people. At present, amyloid PET is not indicated in patients with preclinical AD or healthy subjects, except for clinical trials or research studies. The appropriate usage criteria for amyloid PET were proposed by the Amyloid Imaging Task Force, the Society of Nuclear Medicine and Molecular Imaging, and the Alzheimer’s Association. These criteria indicate that appropriate use of amyloid PET includes the following: 1) patients with persistent or progressive unexplained MCI; 2) patients with possible AD with unclear clinical presentation, either an atypical clinical course or an etiologically mixed presentation; and 3) patients with progressive dementia and atypically early age of onset. Inappropriate use of amyloid PET includes the following: 1) in patients with typical probable AD, 2) for determining the severity of dementia, 3) in subjects with a positive family history of dementia or the presence of $APOE$ e4, 4) in patients with a cognitive problem that is unconfirmed on clinical examination, 5) as a replacement for genotyping for suspected autosomal mutation carriers, 6) in asymptomatic subjects, and 7) for nonmedical use (eg, legal, insurance coverage, or employment screening).

**Dementia with Lewy Bodies**

Dementia with Lewy bodies is the second most common neurodegenerative dementia following AD and is characterized pathologically by the presence of Lewy bodies in cortical, subcortical, and brain stem structures. DLB belongs to the spectrum of Lewy body diseases including Parkinson disease (PD), where Lewy bodies remain in the brain stem. PD with dementia has the same pathology as DLB, though clinical symptoms slightly differ: Parkinsonism appears $\geq$1 year earlier than cognitive dysfunctions in PD with dementia.

In 2005, the criteria for clinical and pathologic diagnoses were revised and included an important role for functional and morphologic imaging. For example, low dopamine transporter uptake in the basal ganglia on SPECT and PET imaging scans is regarded as a suggestive feature for DLB, while supportive features include relative preservation of medial temporal lobe structures on CT/MR imaging and generalized low uptake on SPECT/PET, with reduced occipital activity and abnormal (low) uptake on metadobenzylguanidine myocardial scintigraphy. Relative preservation of the hippocampus in DLB compared with prominent hippocampal atrophy in AD is also a common finding, though there are many overlapping areas of hippocampal atrophy between patients with DLB and those with AD, making it impossible to distinguish a patient with DLB from one with AD by using only a finding of hippocampal atrophy.

The hypometabolic regions in patients with DLB are similar to those in AD, though patients with DLB exhibit a difference in the involved occipital lobe (Fig 5). The relative metabolic reduction was more severe in the occipital cortices and less severe in the medial temporal lobes in DLB compared with AD, and occipital hypometabolism is a key feature of DLB that discriminates it from

**FIG 5.** Decreased glucose metabolic regions of DLB ($n = 20$). Statistical parametric maps show the areas where glucose metabolism is significantly decreased compared with age-matched healthy controls ($n = 20$). The red area indicates the parietotemporal association area, and the posterior cingulate gyri overlap the area where glucose metabolism is decreased in AD. The blue area indicates occipital cortices that are specific for DLB, where the glucose metabolism is preserved in AD ($n = 20$).

AD. Nevertheless, pathologically, the occipital cortices are not as involved in patients with DLB. These findings are also seen in patients with PD and PD with dementia because DLB and PD with dementia are in the same disease entity, involving spread of Lewy bodies in the cerebral cortices.

Dopamine transporter imaging with $^{123}$I-N-ω-fluoropropyl-2β-carbomethoxy-3β-(4-iodophenyl)nortropane ($^{123}$I FP-CIT) SPECT imaging is useful for diagnosing DLB and exhibits a diagnostic accuracy sufficient to distinguish DLB from AD. However, this imaging technique cannot distinguish other degenerative dementias with Parkinsonism (eg, progressive supranuclear palsy (PSP) and multiple system atrophy), while FDG-PET imaging can distinguish DLB from PSP and multiple-system atrophy. $^{123}$I-metabolobenzylguanidine cardiac scintigraphy, which is typically used for myocardial innervation, also demonstrates a high sensitivity and specificity in patients with suspected DLB and provides an accurate examination for differential diagnosis between DLB and other dementias.

**Amyloid Imaging in Dementia with Lewy Bodies**

Shimada et al reported that amyloid deposits are associated with AD-like atrophy in patients with DLB/PD with dementia. Patients with DLB have higher amyloid deposits than patients with PD and PD with dementia. Amyloid deposits have been linked to cognitive impairment in DLB and may contribute to the timing of the onset of dementia relative to that of Parkinsonism in Lewy body dementia. However, as shown in Fig 6, severe metabolic reduction was seen in some patients with DLB despite no evidence of amyloid deposits. In particular, regional metabolic reduction in patients with DLB was observed in the parietotemporal, posterior cingulate, and frontal association cortices, which are the same regions affected in AD but are not correlated with amyloid deposit.

**Frontotemporal Lobe Degeneration**

Frontotemporal lobe degeneration (FTD) is a heterogeneous group of diseases involving frontal and/or anterior temporal lobe degeneration and associated dementia. Frontotemporal dementia is a comprehensive clinical entity of primary degenerative dementia characterized by peculiar behavioral changes and includes 3 types of histologic change (pick-type, frontal lobe degeneration type, and motor neuron disease type). Frontotemporal lobe degeneration includes FTD, semantic dementia, and progressive nonfluent aphasia, while FTD is now used clinically to classify patients with frontal and temporal symptoms.

In FTD, frontal and anterior temporal glucose metabolism is decreased, though the medial temporal region and the subcortical structures, including the striatum and thalamus, are also affected (Fig 7). According to a VBM study of FTD, metabolic and atrophic changes occur in the bilateral frontal and temporal lobes,

**FIG 6.** PiB-PET and FDG-PET images of patients with DLB. Upper row shows a 76-year-old man with DLB. This patient has Parkinsonism and cognitive fluctuation. His Mini-Mental State Examination score was 19. Diffuse glucose metabolic reduction is demonstrated in all regions apart from the striatum and primary sensorimotor cortices (upper left). PiB-PET (upper right) demonstrates a negative amyloid deposit. Lower row shows a 77-year-old woman with DLB, Parkinsonism, and cognitive fluctuation. Her Mini-Mental State Examination score was 23. FDG-PET demonstrates decreased glucose metabolism in the parietotemporal and frontal association cortices, occipital cortices, and posterior cingulate gyrus, while metabolism in the striatum and primary sensorimotor metabolism is spared (lower left). PiB-PET demonstrated diffuse amyloid deposition in the cerebral cortices (lower right).

**FIG 7.** Hypometabolic regions in FTD. Statistical parametric mapping analysis shows hypometabolic regions in patients with FTD ($n = 14$) compared with healthy age-matched subjects ($n = 20$). Glucose metabolism in subjects with FTD was significantly decreased in the bilateral lateral and medial frontal cortices, the posterior cingulate gyrus, and small regions in the parietal association cortices.
whereas the affected regions of metabolism are larger and more severe than those of atrophy in the frontal lobe. In patients with semantic dementia, asymmetrically severely decreased temporal metabolism can be demonstrated on FDG-PET images (Fig 8). These areas can spread to the frontal and parietal cortices, though the degree of metabolism alteration is not as marked as in the anterior temporal cortices.

Amyloid Imaging in Frontotemporal Lobe Degeneration

In a study of PiB retention in patients with FTD, Engler et al reported that most patients with FTD displayed no PiB retention and that PiB could potentially aid in differentiating FTD and AD. Rabinovici et al also reported that 8/12 patients with frontotemporal lobe degeneration had negative amyloid deposits, and the 4 PiB-positive patients with frontotemporal lobe degeneration may suggest the mimicking of AD pathology.

Progressive Supranuclear Palsy

Progressive supranuclear palsy is a neurotrophic degenerative disorder presenting with Parkinsonism and dementia. The neurologic features include impaired ocular motility, pseudobulbar palsy, and axial dystonia. The basal ganglia and brain stem are the main loci of pathologic involvement. MR imaging studies demonstrate brain stem atrophy with a so-called “humming bird” sign, though these findings are not often seen at the early stage of PSP. However, FDG-PET demonstrates decreased glucose metabolism in the midbrain, the lateral and medial frontal lobes, and the caudate nucleus, even at the early stage of PSP (Fig 9) and can distinguish PSP from other diseases with Parkinsonism.

Corticobasal Degeneration

Corticobasal degeneration (CBD), which belongs to the corticobasal syndrome, is characterized by akineto-rigid syndrome, dystonia, myoclonus, apraxia, alien limb syndrome, and cortical sensory loss, and typically occurs with asymmetric onset. CBD is pathologically a tauopathic neurodegenerative disease and includes τ-immunoreactive neuronal cytoplasmic inclusions, oligodendroglial inclusions, and astrocytic plaques. FDG-PET demonstrates hypometabolism in the frontal and parietal cortices and the subcortical structures, including the thalamus, caudate nucleus, and putamen, with marked asymmetry between the 2 hemispheres. Patients with CBD with symptoms of dementia show an AD-like metabolic reduction pattern but asymmetric glucose-metabolic reduction in the lateral frontal, lateral temporal, medial and lateral parietal cortices; the pre- and postcentral gyri; and the thalamus on FDG-PET.

Amyloid Imaging in Progressive Supranuclear Palsy and Corticobasal Degeneration

PSP and CBD are tauopathic neurodegenerative diseases that exhibit no amyloid deposition. If amyloid deposition is demonstrated with amyloid PET, it should be considered small amyloid deposits with age-related amyloid pathology or extended amyloid deposits similar to those in AD due to comorbidity of AD, which may be associated with APOE e4.

Idiopathic Normal Pressure Hydrocephalus

Idiopathic normal pressure hydrocephalus is characterized by disproportionally enlarged cerebrospinal spaces, ventricle and Sylvian fissure dilation, and tight sulci at high convexity in the medial parietal sulci. To detect these features, morphologic images by using CT or MR imaging are necessary. On the other hand, functional images are not necessary because the glucose metabolic reduction pattern is heterogeneous in idiopathic normal pressure hydrocephalus. Glucose metabolism in idiopathic normal pressure hydrocephalus before and after a
shunt operation is promptly reversible after surgery, and there is a relationship between the early metabolic changes and clinical symptoms that is independent of the simultaneous changes in ventricular size. Because idiopathic normal pressure hydrocephalus occurs in elderly individuals, there is a possibility for concomitant AD. Amyloid imaging with PET may be useful to detect early concomitant AD and other diseases associated with amyloid deposits.

Vascular Dementia
Vascular dementia is diagnosed with clinical symptoms and by detecting symptoms related to vascular lesions demonstrated by morphologic imaging. As such, pure vascular dementia is not a PET-applicable dementia. However, vascular dementia is sometimes associated with AD or other neurodegenerative pathology, and these patients should be examined with FDG-PET to determine the comorbidity of AD or other neurodegenerative pathology. Amyloid imaging can be used to remove the comorbidity of AD pathology when there is no amyloid deposit.

Tau Imaging
After amyloid plaques, intracellular neurofibrillary tangles are an important hallmark of AD. Neurofibrillary tangles are preferentially located in the hippocampus and associative cortical regions. 18F-2-(1-[6-[(2-[F]Fluoroethyl)](methyl)amino]-2-naphthyl)-ethylidene)malononitrile or FDDNP was initially developed for Aβ imaging, though this ligand binds to both Aβ plaques and neurofibrillary tangles in the brain. As such, FDDNP was expected to demonstrate both amyloid and neurofibrillary tangle deposits but has limited value for accurate measurement of τ-related pathology in patients with AD. 18F-THK-523 was developed as a potential in vivo imaging probe for τ pathology and was reported to accumulate in regions containing a high attenuation of τ protein deposits. This tracer is now being used in patients with AD. Some forms of FTD, PSP, and CBD are also characterized by pathologic accumulation of τ protein. Thus, τ imaging will be useful in distinguishing these diseases from AD.

Cost-Effectiveness of PET Imaging for Dementia
Silverman et al reported that the introduction of FDG-PET into the clinical work-up of patients with suspected AD can result in substantial benefit in terms of health care cost savings and in benefit for the patient. For the present, there is still no radical treatment for AD because diagnosis of early or preclinical dementia remains controversial. Multicenter cohort studies should be performed to evaluate the cost-effectiveness of new biomarkers such as amyloid PET for early diagnosis of AD and other neurodegenerative demen- 
tias and to establish appropriate PET use criteria for the benefit of patients.

CONCLUSIONS
The use of PET enables the early detection of pathophysiologic changes in patients with dementia and allows differential diagnosis among neurodegenerative demen- 
tias. A summary of FDG-PET and amyloid PET findings for each neurodegenerative dementia is shown in Table 2. Each disease has characteristic regional metabolic reduction patterns on FDG-PET. PET is now used as an in vivo imaging technique for examining neurodeger-
nerative dementia including AD and for detecting the early symptomatic and preclinical stages of dementia.
