Asymptomatic COVID-19: What the Neuroradiologist Needs to Know about Pulmonary Manifestations

R.F. Barajas, Jr, G. Rufener, J. Starkey, T. Duncan, and C. Fuss

ABSTRACT

SUMMARY: Coronavirus disease 2019 (COVID-19) is an infectious disease with a high asymptomatic incidence. Asymptomatic infections within a population will inevitably lead to diagnosis via unrelated medical imaging. We report the case of an asymptomatic patient undergoing a spine CT examination for trauma who was incidentally found to have lung abnormalities later confirmed to be COVID-19. We aim to familiarize neuroradiologists with the spectrum of COVID-19 pulmonary manifestations that are likely to be observed on neck and spine CT imaging.

ABBREVIATIONS: COVID-19 = coronavirus disease 2019; GGO = ground glass opacities; SARS-CoV-2 = Severe Acute Respiratory Syndrome–coronavirus 2

A novel coronavirus, Severe Acute Respiratory Syndrome–coronavirus 2 (SARS-CoV-2) or World Health Organization designated coronavirus disease 2019 (COVID-19) has developed into a pandemic. Initial reports suggest that COVID-19 is a highly infectious disease transmitted through respiratory droplets and fomites, resembling the spread of influenza. Unlike influenza, COVID-19 appears to have a prolonged incubation period with a median of 5.1 days but up to 14 days from exposure. The transmission rate is likely heightened by infected patients demonstrating little or no respiratory symptoms. The rate of asymptomatic infections remains unknown; however, data from the Diamond Princess Cruise Ship and Washington State Skilled Nursing Facility cohorts suggest that approximately 50% of the patients with confirmed COVID-19 were asymptomatic at the time of diagnosis.

The potential of a highly infectious disease spreading via asymptomatic carriers poses unique challenges in the radiologic setting because risk stratification and isolation protocols depend on a suggestive clinical history. Likewise, the presence of a large, asymptomatic cohort will inevitably lead to incidental diagnoses.

We report the case of an asymptomatic patient undergoing a cervical spine CT examination for trauma who was incidentally found to have lung abnormalities, later confirmed to be COVID-19. Given the escalating incidence, the aim of this report is to familiarize neuroradiologists with the spectrum of COVID-19 pulmonary manifestations that are likely to be observed on neck and spine CT examinations.

Brief Report

An 83-year-old man with a history of chronic obstructive pulmonary disease and diabetes mellitus type 2 presented to our institution with 3 days of progressive altered mental status culminating in a fall from standing. A chronic infrequent dry cough was reported, but acute respiratory symptoms were denied. Initial physical examination and vital sign assessment were unremarkable. CT of the cervical spine for suspected traumatic injury showed incidental lung findings of peripheral bilateral apical ground glass opacities (GGO) with a crazy paving appearance (Figure). The reporting neuroradiologist (R.F.B., Jr) consulted the cardiothoracic radiology section chief (C.F.) regarding possible COVID-19 infection. It was agreed that the recently published Radiological Society of North America (RSNA) Expert Consensus Statement on Reporting Chest CT Findings Related to COVID-19 should be used. The treating emergency medicine physician was notified of the high suspicion for COVID-19.
COVID-19 viral pneumonia, and standard protocols for infection and exposure control were initiated.

On the same day, a GeneXpert test (Cepheid) was reported positive for COVID-19 (SARS-CoV-2). The patient was admitted to the medical intensive care unit because of age and comorbidities. Findings of a standard viral panel were negative, including influenza A and B. Labs were notable for thrombocytopenia, mild leukopenia, and mildly elevated D-dimer levels. An experimental course of hydroxychloroquine was initiated. On hospital day 3, the patient experienced a fever of 38.9°C with waxing and waning delirium. Nevertheless, the patient remained on room air without shortness of breath or progressive respiratory symptoms. The patient remains in the medical intensive care unit at the time of this writing.

**DISCUSSION**

Our case highlights the importance of the neuroradiologist being familiar with pulmonary CT findings associated with COVID-19. The neuroradiologist may be the first provider to recognize the possibility of a COVID-19 infection. This role places the responsibility of alerting the treating physician so that standard operating procedures for infection and exposure control can be initiated.

The RSNA Expert Consensus Statement on Reporting Chest CT Findings Related to COVID-19 has recently provided an up-to-date summary of published literature.6 Patients with symptomatic COVID-19 infections typically present with GGO with or without superimposed consolidations. Pulmonary consolidation has been reported as peripheral, posterior, and diffuse with a predominate lower lung zone distribution. The GGO can have a rounded morphology with superimposed inter- or intralobular septal thickening, termed “crazy paving.” The GGO associated with COVID-19 do not seem to follow a perihilar pattern. Later stages of the disease can demonstrate an organizing pneumonia manifested by a “reversed halo sign” or “atoll sign.” The aforementioned pulmonary CT findings are neither sensitive nor specific. Indeed, GGO and crazy paving are observed in many viral lung infections and inflammatory diseases.

The RSNA Expert Consensus Statement on Reporting Chest CT Findings Related to COVID-19 has provided structured language to assist radiologists in reducing reporting variability and uncertainty (Table).6 While focused on the reporting of chest CT findings, it could also be useful to the neuroradiologist in describing incidentally observed pulmonary abnormalities. Four reporting categories based on pulmonary CT findings have been proposed, and reporting language is suggested. We propose, in the context of the ongoing pandemic, that the presence of typical and indeterminate pulmonary imaging findings on neck or spine CT examinations should prompt the neuroradiologist to discuss the possibility of COVID-19 infection with the treating physician in an expedited manner. Pulmonary manifestations of COVID-19 seem to be dependent on the patient’s disease state at the time of imaging. A comprehensive study of pulmonary findings in asymptomatic patients with COVID-19 has not been reported.
As of April 2020, the RSNA, Society of Thoracic Radiology, and the American College of Radiology (ACR) recommend against CT imaging being used to screen for or as a first-line test to diagnose COVID-19. The ACR highlights the limitations of using CT for COVID-19 diagnosis. Normal findings on chest CT do not mean that an individual does not have a COVID-19 infection. Likewise, abnormal CT findings are not sufficiently specific to establish the diagnosis.

In conclusion, ground glass opacities, crazy paving, and organizing pneumonia encountered on pulmonary CT scans should prompt consideration of COVID-19 infection in the current pandemic, with expedited communication with the referring providers and follow-up testing as appropriate.
