A Diagnostic Algorithm for Posterior Fossa Tumors in Children: A Validation Study

AJNR Am J Neuroradiol  published online 4 March 2021
http://www.ajnr.org/content/early/2021/03/04/ajnr.A7057
ABSTRACT

BACKGROUND AND PURPOSE: Primary posterior fossa tumors comprise a large group of neoplasias with variable aggressiveness and short and long-term outcomes. This study aimed to validate the clinical usefulness of a radiologic decision flow chart based on previously published neuroradiologic knowledge for the diagnosis of posterior fossa tumors in children.

MATERIALS AND METHODS: A retrospective study was conducted (from January 2013 to October 2019) at 2 pediatric referral centers, Children’s Hospital of Philadelphia, United States, and Great Ormond Street Hospital, United Kingdom. Inclusion criteria were younger than 18 years of age and histologically and molecularly confirmed posterior fossa tumors. Subjects with no available preoperative MR imaging and tumors located primarily in the brain stem were excluded. Imaging characteristics of the tumors were evaluated following a predesigned, step-by-step flow chart. Agreement between readers was tested with the Cohen $\kappa$, and each diagnosis was analyzed for accuracy.

RESULTS: A total of 148 cases were included, with a median age of 3.4 years (interquartile range, 2.1–6.1 years), and a male/female ratio of 1:24. The predesigned flow chart facilitated identification of pilocytic astrocytoma, ependymoma, and medulloblastoma sonic hedgehog tumors with high sensitivity and specificity. On the basis of the results, the flow chart was adjusted so that it would also be able to better discriminate atypical teratoid/rhabdoid tumors and medulloblastoma groups 3 or 4 (sensitivity = 75%–79%; specificity = 92%–99%). Moreover, our adjusted flow chart was useful in ruling out ependymoma, pilocytic astrocytomas, and medulloblastoma sonic hedgehog tumors.

CONCLUSIONS: The modified flow chart offers a structured tool to aid in the adjunct diagnosis of pediatric posterior fossa tumors. Our results also establish a useful starting point for prospective clinical studies and for the development of automated algorithms, which may provide precise and adequate diagnostic tools for these tumors in clinical practice.

ABBREVIATIONS: AT/RT = atypical teratoid/rhabdoid tumor; LR = likelihood ratio; NPV = negative predictive value; PA = pilocytic astrocytoma; PPV = positive predictive value; WNT = wingless; SHH = sonic hedgehog

In the past 10 years, there has been an exponential increase in knowledge of the molecular characteristics of pediatric brain tumors, which was only partially incorporated in the 2016 World Health Organization Classification of Tumors of the Central Nervous System. The main update in the 2016 Classification was the introduction of the molecular profile of a tumor as an important factor for predicting different biologic behaviors of entities which, on histology, look very similar or even indistinguishable. A typical example is the 4 main groups of medulloblastoma: wingless (WNT), sonic hedgehog (SHH) with or without the p53 mutation, group 3, and group 4. Although they may appear similar on microscopy, these categories have distinct molecular profiles, epidemiology, prognosis, and embryologic origin.

Subsequent to the publication of the 2016 World Health Organization Classification, further studies have identified even more molecular subgroups of medulloblastoma with possible prognostic implications and also at least 3 new molecular subgroups of atypical teratoid/rhabdoid tumor (AT/RT) and several subgroups of ependymoma. MR imaging shows promise as a technique for differentiating histologic tumors and their molecular subgroups. This capability relies on not only various imaging characteristics but also the location and spatial extension of the tumor, evident on MR imaging, which can be traced to the embryologic origin of the neoplastic cells.
One approach to the challenge of identifying imaging characteristics of different tumors in children is to use artificial intelligence. Yet despite this exciting innovation, correctly identifying the location of the mass and its possible use as an element for differential diagnosis still requires the expertise of an experienced radiologist. Previously, D’Arco et al proposed a flow chart (Fig 1) for the differential diagnosis of posterior fossa tumors in children based on epidemiologic, imaging signal, and location characteristics of the neoplasm. The aims of the current study were the following: 1) to validate, in a retrospective, large cohort of posterior fossa tumors from 2 separate pediatric tertiary centers, the diagnostic accuracy of that flow chart, which visually represents the neuroradiologist’s mental process in making a diagnosis of posterior fossa tumors in children, 2) to describe particular types of posterior fossa lesions that are not correctly diagnosed by the initial flow chart, and 3) to provide an improved, clinically accessible flow chart based on the results.

**MATERIALS AND METHODS**

**Setting and Subjects**

A retrospective, cross-sectional study from 2 large tertiary referral pediatric hospitals in 2 countries (Children’s Hospital of Philadelphia, United States, and Great Ormond Street Hospital, London, United Kingdom) was performed on the basis of patient records spanning January 2013 to October 2019 in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement. This study was conducted under 2 research protocols (IRB No. 18–015588 and CA Reg No. 2504), approved by the respective institutional review boards at each center.

Subjects were identified by electronic search of brain MR imaging reports and the electronic health record systems. The following terms/diagnoses were used for the search: “brain tumor,” “posterior fossa tumor,” “brain neoplasia,” “posterior fossa neoplasia,” “cerebellar tumor,” “cerebellar neoplasia,” “medulloblastoma,” “AT/RT,” “atypical teratoid/rhabdoid tumor,” “ependymoma,” “pilocytic astrocytoma.” Results were screened, and subjects younger than 18 years of age with a histologically and genetically confirmed diagnosis of posterior fossa tumor, according to the 2016 World Health Organization classification, were selected. Subjects with no available preoperative MR imaging study, those with low-quality MR imaging studies, and those without diffusion imaging on their MR imaging study were excluded. Subjects with tumors located primarily in the brain stem were also excluded.

**Variables**

Age at first MR imaging (before histologic/pathologic confirmation of the tumor), sex, and histologic and genetic/molecular results...
were obtained from the electronic medical records. Two experienced pediatric neuroradiologists independently reviewed these initial MR imaging studies at each institution (C.A.P.F.A., A.V., F.D., and U.L.), blinded to the final diagnosis. Imaging characteris-
tics were evaluated following a step-by-step numeric flow chart, with a digit assigned to each level and subsequent branch, provid-
ing a flow chart and a 3-digit numeric sequence code for each diag-
nosis end point to be used in the analysis (Fig 1). The flow chart took into account the following: 1) tumor location, 2) ADC map signal intensity in comparison with gray matter, 3) internal archi-
tecture, 4) contrast enhancement, and 5) the patient’s age. The flow chart was designed before the initiation of the study; it was
based on a review on the topic by D’Arco et al. Before starting
the blinded analysis of the cohort, one of the readers (C.A.P.F.A.)
performed a pilot evaluation using the first 8 cases from each insti-
tution (16/148; 10.8%) to confirm the applicability of the flow chart
multiple weeks before the formal evaluation.

Statistical Analysis
Visual inspection of the histogram showed non-normal distribu-
tion, which was confirmed with the Shapiro-Wilk test (P < .001)
for all numeric variables. Categoric variables are described with
percentage and frequency, and numeric variables, with median
and interquartile range. Statistical analysis was performed using
R statistical and computing software, Version 3.5.3 for Windows
(http://www.r-project.org/).

Diagnostic accuracy of the flow chart was verified through a 2 ×
2 contingency table and calculation of sensitivity, specificity, posi-
tive predictive values (PPV), and negative predictive value (NPV).
To estimate accuracy and effect size, we estimated 95% CIs for sen-
sitivity, specificity, PPV, and NPV. The diagnostic accuracy analysis
was performed for each diagnosis, with molecular/histologic diag-
nosis as the criterion standard comparison. Because flow chart
numeric sequences 312 and 311 of the predesigned flow chart
would not provide a single unique final tumor molecular diagnosis,
we later adjusted the sequences according to the most prevalent di-
agnosis. The modified flow chart reflects these adjustments. Last,
we recalculated diagnostic accuracy tests on the basis of the adjust-
ments for these 2 flow chart modifications. The clinical applicability
of findings was further explored with positive and negative likeli-
hood ratios (LR+ and LR−, respectively), and on the basis of changes in probability from the LR described by McGee. Clinical
applicability to rule in diagnosis was considered if the 95% CI of
LR+ was above 10. Clinical applicability to rule out diagnosis
was considered if the 95% CI of LR− was below 0.5.

RESULTS
Histologic Diagnosis and Demographics
One hundred forty-eight subjects were included. The median age
at MR imaging was 3.4 years, (interquartile range = 2.1–6.1 years),
and the male/female ratio was 1.24. Fifty-four (36.5%) patients
had a histologic diagnosis of medulloblastoma, 56 (37.5%) had pilo-
цитic astrocytoma (PA), 12 (8.1%) had AT/RT, and 19 (12.8%)
had ependymoma. Medulloblastomas were also subclassified
according to molecular subtypes including 14/54 (26%) SHH; 7/54
(13%) WNT; 5/54 (9%) group 3; 9/54 (17%) group 4; and 19/54
(35%) group 3 or 4 (separation of groups 3 and 4 was not always
easily possible). Seven cases (5%) had a diagnosis of other tumors
not covered by the flow chart (2 low-grade diffuse astrocytomas
not otherwise specified, 1 hemangioblastoma, 2 gangliogliomas, 1
case of Langerhans cell histiocytosis, and 1 meningioma). Agreement
between readers at each institution was very high (κ = 0.96 for both institutions, P < .001). Because both institutions had
almost perfect agreement, we did a pooled analysis without differ-
entiating per institution. The same diagnosis using the predesigned
flow chart was reached for 86% of the cohort. In the 14% of cases
in which the same diagnosis was not reached by the 2 readers,
disagreement was solved through consensus between the readers.

Diagnosis Using the Flowchart
By means of the predesigned flow chart (Fig 1), the most com-
mon diagnosis was PA (numeric sequence 123) (n = 53, 36%),
followed by medulloblastoma all subgroups (numeric sequence
312) (n = 35, 24%), ependymoma (numeric sequence 323)
(n = 17, 11%), medulloblastoma SHH (numeric sequence 111)
(n = 10, 7%), medulloblastoma group 4 or AT/RT (numeric
sequence 311) (n = 5, 3%), AT/RT (numeric sequence 411) (n = 7,
5%), ependymoma (numeric sequence 423) (n = 7, 5%), desmo-
plastic medulloblastoma SHH (numeric sequence 112) (n = 6,
4%), desmoplastic medulloblastoma SHH (numeric sequence 313)
(n = 3, 2%), and medulloblastoma WNT (numeric sequence 412) (n = 5,
3%). Figure 2 and Table 1 show the statistical results of the sensitiv-
ity, specificity, PPV, and NPV of the flow chart per diagnosis.

In cases that followed sequence 311 (medulloblastoma group
4 or AT/RT), 3/5 (60%) were AT/RT, 1/5 (20%) was an ependy-
moma, and 1/5 (20%) was a medulloblastoma group 4. This find-
ing suggested that sequence 311 catches more tumors in the AT/
RT category than in medulloblastoma group 4, so we reca-
culated the diagnostic accuracy tests considering both 311 and 411 as
AT/RTs. As can be appreciated in Fig 2 and Table 1, diagnostic
accuracy for cases of AT/RT improved when combining sequen-
ces 311 and 411. Of the 35 cases under sequence 312 (medullob-
blastoma all subgroups), 26/35 (74%) were confirmed as group 3
or 4 (3 confirmed as group 3, eight confirmed as group 4, and 15,
as group 3 or 4). The remaining cases under sequence 312 were
3/35 (9%) SHH, 5/35 (14%) WNT, and 1/35 (3%) AT/RT. Figure
3 shows the diagnostic accuracy of sequence 312 to identify
medulloblastoma SHH, WNT, and group 3 or 4. For this
sequence, the NPV and specificity were higher than the PPV and
sensitivity for all other sequences. Table 2 shows the LR analysis
per diagnosis and the recommended sequences for the diagnosis.
After our analysis and on the basis of Table 1 results, we modified
the predesigned flow chart with more precise categorization of the
types of tumor. We recommend this new flow chart (Fig 4)
for the diagnosis of posterior fossa tumors in children.

Some examples of differentiating posterior fossa tumors from
our cohort, diagnosed on the basis of the new flow chart here pre-
presented, can be seen in Figs 5 and 6.

DISCUSSION
The 2016 introduction of the new classification of brain tumors
based on histologic and molecular characteristics dramatically
changed the management of pediatric brain tumors.1,2,14,15 Tumors with similar histologic appearance being related to
completely different cellular populations with different molecular profiles and different embryologic origins implies that they develop along different cellular paths. Thus, tumors that were previously considered as a single group can now be differentiated on imaging by location, age, and/or the patient’s signal characteristics, resulting in a more accurate prognosis.16-18

In light of the crucial role of molecular profiling in tumor diagnosis and management, we found that the predesigned flow chart was very useful for categorizing and better understanding pediatric brain tumors. The importance of molecular profiling in the pediatric neuro-oncology clinical practice was first studied in medulloblastomas but is now recognized for ependymomas, low-grade astrocytomas, AT/RTs, and all previously classified primitive neuroectodermal tumors.6,18-22

Yet, since the 2016 classification update, several newly identified radiologic markers have been proposed as surrogates for the molecular diagnosis. The role of these radiologic markers may be limited by the constant evolution of the molecular characterization of brain tumors.8,11 However, we believe that a standardized method of evaluating images, such as the proposed flow chart, may facilitate increased diagnostic accuracy.

The initial predesigned diagnostic flow chart has proved reliable and consistently accurate in this validation study, with an almost perfect agreement between 2 blinded neuroradiologists at 2 different institutions. Our results showed high coefficients of specificity and NPV for all diagnoses included in the predesigned flow chart. Sensitivity coefficients were high (>87%) for diagnosing pilocytic astrocytoma and ependymomas, the 2 most common diagnoses in

FIG 2. Diagnostic accuracy of a predesigned radiologic flow chart to identify different types of cerebellar tumors.
Moreover, PA and ependymoma tumors had the smallest 95% CIs, suggesting reliability in the diagnosis of these 2 types of tumors. This was especially true for PA, in which the lower 95% CI limit for sensitivity was 76%, and for PPV, it was 82%.

After analyzing results from the initial flow chart created on the basis of more recently published literature, we modified it to improve diagnostic accuracy. Our modifications (see Figs 1 and 4 for comparison) successfully improved the sensitivity coefficient for identification of AT/RTs to 75%, but the confidence interval remained wide. The second modification to flow chart sequence 312 made possible the identification of most cases of medulloblastoma group 3 or 4, with fair-to-good sensitivity (61%–91%) and PPV (57%–88%) and good-to-excellent specificity (86%–96%) and NPV (88%–97%). The modified flow chart proved to be more clinically relevant. The modified flow chart proved capable of discriminating AT/RTs, ependymomas, medulloblastomas SHH, medulloblastoma groups 3 and 4, and PA, which together constitute 90.5% of tumors in our cohort. Clinically, the flow chart demonstrates great performance in ruling out group 3 or 4 medulloblastomas, PAs, and ependymomas and ruling in AT/RTs.

However, when it came to correctly identifying WNT medulloblastoma (numeric sequence 412, Fig 2), diagnostic accuracy was poor. In the predesigned flow chart, the authors designated a tumor in the pontocerebellar angle/foramen of Luschka with high cellularity (ie, low ADC) and patient age older than 3 years as suggestive of WNT. The rationale was that the cellular path of embryologic precursors, which can transform into neoplastic WNT cells, arises from the fourth ventricle down and laterally into the foramen of Luschka. However, our cohort. Moreover, PA and ependymoma tumors had the smallest 95% CIs, suggesting reliability in the diagnosis of these 2 types of tumors. This was especially true for PA, in which the lower 95% CI limit for sensitivity was 76%, and for PPV, it was 82%.

After analyzing results from the initial flow chart created on the basis of more recently published literature, we modified it to improve diagnostic accuracy. * Clinically applicable confidence intervals.
The only other tumor with striking diffusion restriction in the Luschka area is AT/RT, but this is typical of younger children. These results can be explained by several factors: the small number of WNT tumors present in our series (10% of all medulloblastomas), most cases in our series being in the fourth ventricle (which is understandable given that the path of the WNT cells is thought to start from the fourth ventricle), and the presence of anaplastic ependymomas showing diffusion restriction (therefore simulating WNT medulloblastoma on imaging). More recently, a study of a larger cohort of WNT medulloblastomas has shown that they are not as lateralizing as previously reported in smaller cohorts. This study has some limitations, the main one being its retrospective nature. However, we controlled potential biases by doing a blinded review of images by only including cases with images obtained before surgical intervention and creating the baseline flow chart before data collection. Another important limitation is the relatively small number of cases for some types of tumor, which explains the larger confidence intervals for certain tumors. Nevertheless, many pediatric cerebellar tumors are relatively rare, and this is perhaps one of the largest cohorts available in the literature. Moreover, we were able to gather a large enough cohort to allow diagnostic accuracy tests for the most common types of pediatric cerebellar tumors, with reliable results for most diagnoses.

Because this was planned as a validation study, we consider it successful in providing results that show that the modified flow chart can be used, is reliable, and has clinical applicability.

More research is still desired, with a larger consistency analysis evaluating results from multiple blinded readers. A larger prospective study would be needed to evaluate the diagnostic efficacy of the modified flow chart with higher precision. Such a study could provide an initial decision model for potential deep learning studies. Artificial intelligence is already being used to predict the molecular profile of brain tumors, most commonly in adult populations, but with recent important studies emerging in pediatric populations. The main limitation for the application of machine learning in posterior fossa tumors may be the identification of tumor location, because we know that signal characteristics (which reflect at least partially histologic appearances) can be similar for different molecular groups with similar tissue features. Currently, artificial intelligence is not able to differentiate tumors with the necessary level of precision, though this may be possible in the future.

**CONCLUSIONS**

A flow chart for the diagnosis of posterior fossa tumors in children has been validated through a retrospective analysis of 148 patients with confirmed diagnoses. On the basis of analysis of these
FIG 5. Differential diagnoses in cases of posterior fossa tumors originating from the cerebellar hemisphere. Axial T2WI (A) and axial ADC map (B) show SHH medulloblastoma (flow chart 2, number 111) in a typical peripheral location within the cerebellar hemisphere due to its origin from ganglionic cell precursors. Note very low ADC values (ie, diffusion restriction). Axial T2WI (C) and axial ADC map (D) show the typical appearance of a pilocytic astrocytoma (flow chart 2, number 123) originating from the cerebellar hemisphere. Note the typical nodule and appearance of cysts and much higher ADC values in comparison with the medulloblastoma.

FIG 6. Differential diagnoses in posterior fossa tumors involving the foramen of Luschka and cerebellopontine angle. Axial T2WI (A) and axial ADC map (B) show SHH medulloblastoma (flow chart 2, number 111) in a typical peripheral location within the cerebellar hemisphere due to its origin from ganglionic cell precursors. Note very low ADC values (ie, diffusion restriction). Axial T2WI (C) and axial ADC maps (D) in a 2-year-old boy with a AT/RT (new flow chart number 411). Note the presence of internal vessels (arrow) and intermediate ADC values. Axial T2 (C) and ADC maps (D) in a 2-year-old boy with a AT/RT (new flow chart number 411). Note the typical nodule and appearance of cysts and much higher ADC values in comparison with the medulloblastoma.

results, the predesigned flow chart was accurate in identifying most diagnoses, and with our subsequent modifications, the overall accuracy improved. The modified flow chart showed a good likelihood ratio for most of the histologic and molecular groups of tumors. Furthermore, it may offer an important starting point for prospective analysis using machine learning techniques. As new molecular subgroups emerge in the classification of pediatric brain tumors, there is the potential for further modifications to the flow chart to aid in diagnosis.
